Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Author assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

The Publisher

Library of Congress Control Number 2007943577

Vice President and Publisher: Linda Duncan

Managing Editor: Teri Merchant

Developmental Editor: Shelly Stringer

Publishing Services Manager: Patricia Tannian

Senior Project Manager: Sarah Wunderly

Design Direction: Amy Buxton

	Front Matter	iv
	PART ONE HISTORY, PHYSICAL EXAMINATION, AND MEDICAL RECORDS	3
1	Chapter 1 Ruminant History, Physical Examination, and Records	3
2	Chapter 2 Equine History, Physical Examination, and Records	15
	PART TWO MANIFESTATIONS Of DISEASE	15
3	Chapter 3 Pain	23
4	Chapter 4 Alterations in Body Temperature	32
5	Chapter 5 Alterations in Respiratory Function	42
6	Chapter 6 Alterations in Cardiovascular and Hemolymphatic Systems	83
7	Chapter 7 Alterations in Alimentary and Hepatic Function	96
8	Chapter 8 Localization and Differentiation of Neurologic Diseases	117
9	Chapter 9 Alterations in Body Weight or Size	147
10	Chapter 10 Alterations in Urinary Function	170
11	Chapter 11 Alterations in the Skin	178
12	Chapter 12 Alterations in Sexual Function	194
13	Chapter 13 Musculoskeletal Abnormalities	217
14	Chapter 14 Collapse and Sudden Death	232
	PART THREE DISORDERS AND MANAGEMENT OF THE NEONATE	232
15	Chapter 15 The Peripartum Period	243

16	Chapter 16 Perinatal Adaptation, Asphyxia, and Resuscitation	252 252
17	Chapter 17 Initial Management and Physical Examination of the Neonate	262 262
18	Chapter 18 Neonatal Infection	281 281
19	Chapter 19 Manifestations and Management of Disease in Foals	293 293
20	Chapter 20 Manifestations and Management of Disease in Neonatal Ruminants	333 333
21	Chapter 21 Colostrum Substitutes and Milk Replacers	367
	PART FOUR COLLECTION OF SAMPLES AND INTERPRETATION OF LABORATORY TESTS	367
22	Chapter 22 Clinical Chemistry Tests	375 375
23	Chapter 23 Collection and Submission of Samples for Cytologic and Hematologic Studies	398 398
24	Chapter 24 Alterations in the Erythron	400 400
25	Chapter 25 Alterations in the Leukogram	405 405
26	Chapter 26 Alterations in Blood Proteins	411 411
27	Chapter 27 Alterations in the Clotting Profile	417 417
28	Chapter 28 Collection and Analysis of Bone Marrow	422 422
29	Chapter 29 Molecular Diagnostics in Large Animals	436
	PART FIVE DISORDERS OF THE ORGAN SYSTEMS	436
30	Chapter 30 Diseases of the Cardiovascular System	453 453
31	Chapter 31 Diseases of the Respiratory System	490 490

32	Chapter 32 Diseases of the Alimentary Tract	667 667
33	Chapter 33 Diseases of the Hepatobiliary System	893 893
34	Chapter 34 Diseases of the Renal System	925 925
35	Chapter 35 Diseases of the Nervous System	972 972
36	Chapter 36 Mammary Gland Health and Disorders	1112 1112
37	Chapter 37 Diseases of the Hematopoietic and Hemolymphatic Systems	1144 1144
38	Chapter 38 Diseases of the Bones, Joints, and Connective Tissues	1189 1189
39	Chapter 39 Diseases of the Eye	1259 1259
40	Chapter 40 Diseases of the Skin	1306 1306
41	Chapter 41 Endocrine and Metabolic Diseases	1339 1339
42	Chapter 42 Diseases of Muscles	1388 1388
43	Chapter 43 Diseases of the Reproductive System	1419
	PART SIX PREVENTIVE AND THERAPEUTIC STRATEGIES	1419
44	Chapter 44 Critical Care and Fluid Therapy for Horses	1487 1487
45	Chapter 45 Principles of Antimicrobial Therapy	1506 1506
46	Chapter 46 Biosecurity and Infection Control for Large Animal Practices	1524 1524
47	Chapter 47 Prevention, Detection, and Response to Foreign Animal Diseases	1551 1551
48	Chapter 48 Use of Biologics in the Prevention of Infectious Diseases	1557 1557
49	Chapter 49 Parasite Control Programs	1623 1623

50	Chapter 50 Nutrition of the Sick Animal	1648
	PART SEVEN CONGENITAL, HEREDITARY, IMMUNOLOGIC, AND TOXIC DISORDERS	1648
51	Chapter 51 Genetic Disorders	1657 1657
52	Chapter 52 Genetic Tests for Large Animals	1660 1660
53	Chapter 53 Immunologic Disorders	1665 1665
54	Chapter 54 Disorders Caused by Toxicants	1691

Contributors

Dorothy Ainsworth, DVM, PhD, DACVIM

Professor of Medicine, Department of Clinical Sciences, College of Veterinary Medicine, Cornell University, Ithaca, New York

Monica Aleman, MVZ, PhD, DACVIM

Senior Veterinarian, Veterinary Medicine and Epidemiology, University of California, Davis, California

Trevor R. Ames, DVM, MS, DACVIM

Professor and Department Chair, Veterinary Population Medicine, College of Veterinary Medicine, University of Minnesota, St. Paul, Minnesota

John A. Angelos, DVM, PhD, DACVIM

Assistant Professor, Veterinary Medicine and Epidemiology, University of California, Davis, California

Jane E. Axon, BVSc (Hons), MACVSc, DACVIM

Director, Clovelly Intensive Care Unit, Scone Veterinary Hospital, Scone, New South Wales, Australia

John C. Baker, DVM, PhD, DACVIM

Associate Director and Professor, Michigan Agricultural Experiment Station, Michigan State University, East Lansing, Michigan

Lora Rickard Ballweber, MS, DVM, DEVPC

Associate Professor and Clinical Parasitologist, Department of Microbiology, Immunology, and Pathobiology, Colorado State University, Fort Collins, Colorado

Danika Bannasch, DVM, PhD

Associate Professor, Department of Population Health and Reproduction, School of Veterinary Medicine, University of California, Davis, California

George M. Barrington, DVM, PhD, DACVIM

Associate Professor, Large Animal Internal Medicine, Department of Veterinary Clinical Sciences, Washington State University, Pullman, Washington

Daniela Bedenice, DVM, DACVIM, DACVECC

Assistant Professor, Department of Clinical Sciences, Large Animal Medicine, Cummings School of Veterinary Medicine, Tufts University, North Grafton, Massachusetts

Steven L. Berry, DVM, MPVM

Extension Dairy Specialist, Dairy Management and Health, Animal Science, University of California, Davis, California

Christine F. Berthelin-Baker, DVM, DACVIM (Neurology), DECVN

Neurologist/Neurosurgeon All Animals Neurology and Neurosurgery Animal Emergency Center Atlanta, Georgia

Andrea A. Bohn, DVM, PhD, DACVP (Clinical Pathology)

Assistant Professor, Department of Microbiology, Immunology, and Pathology, Colorado State University, Fort Collins, Colorado

Carole A. Bolin, DVM, PhD

Professor, Department of Pathobiology and Diagnostic Investigation, College of Veterinary Medicine, Michigan State University, East Lansing, Michigan

Terry L. Blanchard, DVM, MS, DACT

Hill N Dale Farm, Lexington, Kentucky

Anthony T. Blikslager, DVM, PhD, DACVS

Interim Department Head and Associate Professor, Equine Surgery, Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University, Raleigh, North Carolina

James P. Brendemuehl, DVM, PhD, DACT

Assistant Professor, Veterinary Teaching Hospital, College of Veterinary Medicine, Oregon State University, Corvallis, Oregon

Babetta A. Breuhaus, DVM, PhD

Associate Professor, Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University, Raleigh, North Carolina

Steven P. Brinsko, DVM, MS, PhD, DACT

Associate Professor, Large Animal Medicine and Surgery, Texas A&M University, College Station, Texas

Gordon W. Brumbaugh, DVM, PhD, DACVIM, DACVCP

Associate Professor, Veterinary Physiology and Pharmacology, College of Veterinary Medicine, Texas A&M University, College Station, Texas

T. Douglas Byars, DVM, DACVIM, DACVECC

Byars Equine Advisory, LLC, Georgetown, Kentucky

Robert J. Callan, DVM, MS, PhD, DACVIM

Associate Professor, Department of Clinical Sciences, Colorado State University, Fort Collins, Colorado

Gary P. Carlson, DVM, PhD, DACVIM, DACVP

Professor Emeritus, Department of Veterinary Medicine, University of California, Davis, California

Elizabeth A. Carr, DVM, PhD, DACVIM, DACVECC

Assistant Professor, Department of Large Animal Clinical Sciences, College of Veterinary Medicine, Michigan State University, East Lansing, Michigan

Stan W. Casteel, DVM, PhD, DABVT

Professor of Toxicology, Veterinary Medicine Diagnostic Laboratory, College of Veterinary Medicine, University of Missouri, Columbia, Missouri

Christopher Cebra, VMD, MA, MA, DACVIM

Associate Professor, Large Animal Medicine, College of Veterinary Medicine, Oregon State University, Corvallis, Oregon

M. Keith Chaffin, DVM, MS, DACVIM

Professor, Department of Large Animal Clinical Sciences, College of Veterinary Medicine, Texas A&M University, College Station, Texas

Erin S. Champagne, DVM, DACVO

Ophthalmologist, Veterinary Specialists of Western New York, Buffalo, New York

A. Berkley Chesen, DVM

Large Animal Surgery, College of Veterinary Medicine, Texas A&M University, College Station, Texas

Bruce W. Christensen, DVM, MS, DACT

Senior Veterinarian, Goulburn Valley Equine Clinic, Congupna, Victoria, Australia

Anthony W. Confer, DVM, PhD, DACVP

Department Head, Regents Professor and Sitlington Endowed Chair for Food Animal Research, Department of Veterinary Pathobiology, Oklahoma State University, Center for Veterinary Health Sciences, Stillwater, Oklahoma

Vanessa L. Cook, Vet MB, MS, DACVS, DACVECC

Research Associate, Department of Clinical Sciences, North Carolina State University, Raleigh, North Carolina

Kevin T.T. Corley, BVMs, PhD, DACVIM, DACVECC, MRCVS

Anglesey Lodge Equine Hospital, The Curragh, County Kildare, Ireland

Victor S. Cortese, DVM, PhD, DABVP (Dairy)

Director Veterinary Specialty Operations, Cattle Immunology, Pfizer Animal Health, Simpsonville, Kentucky

Beate M. Crossley, DVM, PhD, MPVM

Virologist, California Animal Health and Food Safety Laboratory System, University of California, Davis, California

Robin M. Dabareiner, DVM, MS, PhD, DACVS

Assistant Professor of Lameness, College of Veterinary Medicine, Texas A&M University, College Station, Texas

Andrew J. Dart, BVSc, DVCS, MACVSc, DACVS, ECVS

Senior Registrar, University of Sydney, New South Wales, Australia

Elizabeth J. Davidson, DVM, DACVS

Assistant Professor, Sports Medicine, Department of Clinical Studies, New Bolton Center, University of Pennsylvania, Kennett Square, Pennsylvania

Eric W. Davis, DVM, MS, DACVIM, DACVS

Department of Large Animal Clinical Sciences, University of Tennessee, Knoxville, Tennessee

Jennifer L. Davis, DVM, PhD, DACVIM, DACVCP

Clinical Assistant Professor of Equine Medicine and Pharmacology, Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University, Raleigh, North Carolina

Fabio Del Piero, DVM, Dial. ACVP, PhD

Associate Professor of Pathology, School of Veterinary Medicine, University of Pennsylvania, Kennett Square, Pennsylvania

André Desrochers, DVM, MS, DACVS, DECBHM

Professor, University of Montreal, Faculty of Veterinary Medicine, St-Hyacinthe, Quebec

Thomas J. Divers, DVM, DACVIM, DACVECC

Professor of Medicine, Chief, Section of Large Animal Medicine, Clinical Sciences

College of Veterinary Medicine, Cornell University, Ithaca, New York

Maarten Drost, DVM, DACT

Professor, Emeritus Department of Large Animal Clinical Sciences, College of Veterinary Medicine, University of Florida, Gainesville, Florida

Gerald E. Duhamel, DVM, PhD, DACVP

Professor, Department of Veterinary Biomedical Sciences, University of Nebraska-Lincoln, Lincoln, Nebraska

Bettina Dunkel, DVM, DACVIM, DACVECC

Veterinary Basic Sciences, Royal Veterinary College, University of London, North Mymms, Hertfordshire, United Kingdom

Noel O. Dybdal, DVM, PhD, DACVIM

Genentech, Inc., South San Francisco, California

Joan Dziezyc, DVM, DACVO

Associate Professor, Department of Small Animal Medicine and Surgery, Texas A&M University, College Station, Texas

Jack Easley, DVM, MS, DABVP (Equine)

Owner, Equine Veterinary Practice, Shelbyville, Kentucky

Nancy East, DVM, MPVM, MS

Associate Professor (retired), Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California, Davis, California

Randall B. Eggleston, DVM, DACVS

Assistant Clinical Professor, Large Animal Medicine, College of Veterinary Medicine, University of Georgia, Athens, Georgia

John A. Ellis, DVM, PhD, DACVP, DACVM

Professor, Veterinary Microbiology, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Roger W. Ellis, DVM, MS

Assistant Professor, Extension Veterinarian, Department of Clinical Sciences, Colorado State University, Fort Collins, Colorado

Robert English, DVM, PhD, DACVO

Animal Eye Care Associates, Cary, North Carolina

Anne G. Evans, DVM, MBA, DACVD

Rancho Mirage, California

James F. Evermann, MS, PhD

Professor, Infectious Diseases, Diagnostic MedicineVeterinary Clinical Sciences and Washington Animal Diseases Diagnostic Laboratory, College of Veterinary Medicine, Washington State University, Pullman, Washington

Darien J. Feary, BVSC, MS, DACVIM, DACVECC

Lecturer in Equine Medicine, University Veterinary Hospital, Camden, University of Sydney, Camden, New South Wales, Australia

Gilles Fecteau, DVM, DACVIM

Professor, Department of Clinical Sciences, Université de Montréal, Saint-Hyacinthe, Québec, Canada

C. Langdon Fielding, DVM

Loomis Basin Equine Medical Center, Loomis, California

Sherrill A. Fleming, DVM, DABVP (Food Animal), DACVIM

Associate Professor, Department of Pathobiology and Production Medicine, College of Veterinary Medicine, Mississippi State University, Mississippi State, Mississippi

David Francoz, DMV, MSc, DACVIM

Associate Professor, Département des Sciences Cliniques, Faculté de Médecine Vétérinaire, Université de Montréal, Saint-Hyacinthe, Québec, Canada

Nicholas Frank, DVM, PhD, DACVIM

Assistant Professor, Department of Large Animal Clinical Sciences, University of Tennessee, Knoxville, Tennessee

Francis D. Galey, DVM, PhD, DABVT

Dean, College of Agriculture, University of Wyoming, Laramie, Wyoming

Franklyn Garry, DVM, MS, DACVIM

Professor, Department of Clinical Sciences, Colorado State University, Fort Collins, Colorado

Lisle W. George, DVM, PhD, DACVIM

Professor, Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California, Davis, California

Terry C. Gerros, DVM, DACVIM

Owner and Practitioner, Santiam Equine, Salem, Oregon

E. Paul Gibbs, BVSc, PhD, FRCVS

Professor of Virology Department of Infectious Diseases and Pathology, College of Veterinary Medicine University of Florida, Gainesville, Florida

Steeve Giguère, DVM, PhD, DACVIM

Associate Professor, Director Hofmann Equine Neonatal Intensive Care Unit, Department of Large Animal Clinical Sciences, University of Florida, Gainesville, Florida

Mary Belle Glaze, DVM, MS, DACVO

Gulf Coast Animal Eye Clinic, Houston, Texas

Jesse P. Goff, DVM, PhD

Research Leader, Periparturient Diseases of Cattle Research Unit, National Animal Disease Center, USDA-ARS, Ames, Iowa

Kathleen Casey Gonda, DVM, MS, DACVIM

Specialty Equine Medicine, Keswick, Virginia

Daniel H. Gould, DVM, PhD, DACVP

Professor Emeritus, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, Colorado

Daniel L. Grooms, DMV, PhD, DACVIM

Associate Director, Michigan Agricultural Experiment Station, Assistant Professor, Department of Large Animal Clinical Sciences, College of Veterinary Medicine, Michigan State University, East Lansing, Michigan

Charles L. Guard, PhD, DVM

Associate Professor, Cornell University, Ithaca, New York

Alison A. Gunn, BVSc, MVS, MACVSc

Lecturer in Ruminant Health and Production, Livestock Veterinary Teaching and Research Unit, Faculty of Veterinary Science, University of Sydney, New South Wales, Australia

Spring K. Halland, DVM, DACVIM

Assistant Clinical Professor, Veterinary Population Medicine, College of Veterinary Medicine, University of Minnesota, St. Paul, Minnesota

Joanne Hardy, DVM, PhD, DACVS, DACVECC

Clinical Associate Professor, Large Animal Clinical Sciences, Texas A&M University, College Station, Texas

Arlyn Jud Heinrichs, MS, PhD

Professor of Dairy Science, Department of Dairy and Animal Science, The Pennsylvania State University, University Park, Pennsylvania

Sharon K. Hietala, PhD

Professor of Clinical Diagnostic Immunology, Veterinary Medicine and Epidemiology, University of California, Davis, California

K.W. Hinchcliff, BVSc, MS, PhD, DACVIM

Professor and Dean Faculty of Veterinary Sciences University of Melbourne Melbourne, Victoria, Australia

Melissa T. Hines, DVM, PhD, DACVIM

Associate Professor, Department of Veterinary Clinical Sciences, Washington State University, Pullman, Washington

Charles A. Hjerpe, DVM

Professor Emeritus, School of Veterinary Medicine, University of California, Davis, California

David R. Hodgson, BVSc, PhD, DACVIM, FACSM, MACVSc

Professor of Large Animal Medicine and Director, University Veterinary Centre, Camden, Faculty of Veterinary Science, University of Sydney, Camden, New South Wales, Australia

Patricia M. Hogan, VMD, DACVS

Hogan Equine Clinic at Fair Winds Farm, Cream Ridge, New Jersey

Clifford M. Honnas, DVM, DACVS

Associate Professor, Equine Orthopedic Surgery and Lameness, Large Animal Clinic, Texas A&M University, College Station, Texas

John K. House, BVMS, PhD, DACVIM

Associate Professor, Faculty of Veterinary Medicine, Sydney University, Camden, New South Wales, Australia

Angela M. Hughes, DVM

Veterinary Genetics, Veterinary Medical Teaching Hospital, University of California, Davis, California

Pam Hullinger, DVM, MPVM

Research Scientist, Medical Physics and Biophysics Division, Physics and Advanced Technology Directorate, Lawrence Livermore National Laboratory, Livermore, California

Jared J. Janke, DVM

Veterinary Resident Instructor, Large Animal Clinical Sciences, Texas A&M University, College Station, Texas

Jill R. Johnson, DVM, MS, DACVIM, DABVP

Professor of Equine Medicine, Department of Veterinary Clinical Sciences, Veterinary Teaching Hospital and Clinics, School of Veterinary Medicine, Louisiana State University, Baton Rouge, Louisiana

Janet K. Johnston, DVM, DACVIM

Department of Clinical Studies, New Bolton Center, University of Pennsylvania, Kennett Square, Pennsylvania

Coleen M. Jones, MS

Research Associate, Department of Dairy and Animal Science, The Pennsylvania State University, University Park, Pennsylvania

Samuel L. Jones, DVM, PhD, DACVIM

Assistant Professor of Equine Medicine, College of Veterinary Medicine, North Carolina State University, Raleigh, North Carolina

Will C. Jordan, DVM

Large Animal Clinical Sciences, Texas A&M University, College Station, Texas

Carter E. Judy, DVM, DACVS

Staff Surgeon, Alamo Pintado Equine Medical Center, Los Olivos, California

Steven G. Kamerling, RPh, PhD

Senior Scientist, Discovery Research, Pharmacia Animal Health, Kalamazoo, Michigan

Gabriele A. Landolt, DVM, MS, PhD, DACVIM

Assistant Professor, Department of Clinical Sciences, Colorado State University, Fort Collins, Colorado

V. Michael Lane, DVM, MPVM, DABVP, DACT

Associate Professor of Clinical Reproduction and Herd Health, Veterinary Medicine: Population Health and Reproduction, University of California, Davis, California

Richard A. LeCouteur, BVSc, PhD, DACVIM (Neurology), DECVN

Professor, Surgical and Radiological Sciences, School of Veterinary Medicine, University of California, Davis, California

Guy D. Lester, BSc (Hons), BVMS, PhD, DACVIM

Associate Professor of Equine Medicine, School of Veterinary and Biomedical Sciences, Murdoch University, Murdoch, Western Australia

Christian M. Leutenegger, Dr Vet Med, PhD, FVH

Lead Scientist, Molecular Diagnostic Laboratory, IDEXX, Sacramento, California

Robert L. Linford, DVM, PhD, DACVS

Professor and Chief, Equine Medicine and Surgery, Department of Clinical Sciences, College of Veterinary Medicine, Mississippi State University, Starkville, Mississippi

K.C. Kent Lloyd, DVM, PhD

Associate Professor, Veterinary Anatomy, Physiology, and Cell Biology, Center for Comparative Medicine, School of Veterinary Medicine, University of California, Davis, California

Jeanne Lofstedt, BVSc, MS, DACVIM

Professor of Health Management, Atlantic Veterinary College, University of Prince Edward Island, Atlantic Veterinary College, Charlottetown, Prince Edward Island, Canada

Guy H. Loneragan, BVSc (Hons), MS

Associate Professor and Epidemiologist, Department of Agricultural Sciences, West Texas A&M University, Canyon, Texas

Maureen Long, DVM, MS, PhD, DACVIM

Associate Professor Department of Infectious Diseases and PathologyCollege of Veterinary Medicine, University of Florida, Gainesville, Florida

D. Paul Lunn, BVSc, MS, PhD MRCVS, DACVIM

Professor and Department Head, Department of Clinical Sciences, James L. Voss Veterinary Teaching Hospital, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins, Colorado

John Maas, DVM, MS, DACVN, DACVIM

Extension Veterinarian, School of Veterinary medicine, University of California, Davis, California

Melinda H. MacDonald, DVM, PhD, DACVS

Assistant Professor Equine Surgery, Department of Surgical and Radiological Sciences, School of Veterinary Medicine, University of California, Davis, California

Robert J. MacKay, BVSc, PhD, DACVIM

Professor and Chief, Large Animal Medicine, Department of Large Animal Clinical Sciences, University of Florida, Gainesville, Florida

Jennifer M. MacLeay, DVM, PhD, DACVIM

Associate Professor, Department of Clinical Sciences, Colorado State University, Fort Collins, Colorado

John E. Madigan, DVM, MS, DACVIM

Professor, Department of Veterinary Medicine and Epidemiology, University of California, Davis, California

K. Gary Magdesian, DVM, DACVIM, DACVECC, DACVCP

Lecturer, Equine Medicine and Emergency/Critical Care, Veterinary Medical Teaching Hospital, School of Veterinary Medicine, University of California, Davis, California

David J. Maggs, BVSc(hons), DACVO

Associate Professor, Surgical and Radiological Sciences, University of California, Davis, California

John B. Malone, BS, DVM, PhD

Professor of Veterinary Parasitology, Pathobiological Sciences, School of Veterinary Medicine, Louisiana State University, Baton Rouge, Louisiana

Peggy S. Marsh, DVM, DACVIM

Clinical Assistant Professor, Department of Veterinary Large Animal Clinical Sciences, Texas A&M University, College Station, Texas

Melissa Mazan, DVM, DACVIM

Associate Professor and Director of Equine Sports Medicine Program, Department of Clinical Sciences, Tufts Cummings School of Veterinary Medicine, North Grafton, MA

Craig McConnel, DVM, MVCS

Department of Clinical Sciences, Colorado State University, Fort Collins, Colorado

Patrick M. McCue, DVM, PhD, DACT

Associate Professor, Department of Clinical Sciences, Colorado State University, Fort Collins, Colorado

Dianne McFarlane, DVM, PhD, DACVIM, DABVP

Assistant Professor, Department of Physiological Sciences, Oklahoma State University, Stillwater, Oklahoma

Sheila M. McGuirk, DVM, MS, PhD, DACVIM

University of Wisconsin, School of Veterinary Medicine, Madison, Wisconsin

Nat T. Messer, IV DVM, DABVP

Associate Professor, Department of Veterinary Medicine and Surgery, University of Missouri, Columbia, Missouri

Jason C. Mez, DVM

Veterinary Resident Instructor, Large Animal Medicine and Surgery, Texas A&M University, College Station, Texas

Paul G.E. Michelsen, MS, DVM

Partner, Mendocino Equine Clinic, Redwood Valley, California

Nicholas J. Millichamp, BVetMed, PhD, DVOphthal, DECVO, MRCVS, DACVO

Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, Texas A&M University, College Station, Texas

James N. Moore, DVM, PhD, DACVS

Research Professor, Department of Large Animal Medicine, College of Veterinary Medicine, University of Georgia, Athens, Georgia

Cecil P. Moore, DVM, MS, DACVO

Professor and Chairman, Veterinary Medicine and Surgery, University of Missouri, Director, Veterinary Medicine Teaching Hospital, Columbia, Missouri

Dawn E. Morin, DVMN, MS, DACVIM

Associate Professor, Veterinary Clinical Medicine, College of Veterinary Medicine, University of Illinois at Urbana-Champaign, Urbana, Illinois

Paul S. Morley, DVM, PhD, DACVIM

Associate Professor, Epidemiology and Biosecurity, Director of Biosecurity, James L. Voss Teaching Hospital, Director, Animal Population Health Institute, Department of Clinical Sciences, Colorado State University, Fort Collins, Colorado

Debra Deem Morris, DVM, MS, DACVIM

Chief of Staff, Banfield the Pet Hospital, Chula Vista, California

Derek A. Mosier, DVM, PhD

Professor, Diagnostic Medicine and Pathobiology, Kansas State University, Manhattan, Kansas

Michael Murphy, DVM, PhD, DABVT

University of Minnesota, College of Veterinary Medicine, St. Paul, Minnesota

Michael J. Murray, DVM, MS, DACVIM

Director, Companion Animal Biologicals and Equine Brands, Global Strategic Marketing, Merial Limited, Duluth, Georgia

T.G. Nagaraja, MVSc, PhD

Professor, Diagnostic Medicine and Pathobiology, Kansas State University, Manhattan, Kansas

Mark Nasisse, DVM, DACVO

Staff Ophthalmologist, Carolina Veterinary Specialists, Greensboro, North Carolina

Jonathan A. Naylor, BSc, BVSc, PhD, DACVIM, DACVN

Department of Clinical Sciences, School of Veterinary Medicine, Ross University, Basseterre, St. Kitts

Guy H. Palmer, DVM, PhD

Professor of Microbiology and Pathology, Washington State University, College of Veterinary Medicine, Pullman, Washington

John R. Pascoe, BVSc, PhD, DACVS

Professor of Surgery, Department of Surgical and Radiological Sciences, University of California, Davis, California

Steven M. Parish, DVM, DACVIM

Professor, Large Animal Internal Medicine, Veterinary Teaching Hospital, Washington State University, Pullman, Washington

Michael Payne

Outreach Program Coordinator, Western Institute for Food Safety and Security, University of California, Davis, California

Anthony P. Pease, DVM, MS, DACVR

Assistant Professor in Diagnostic Imaging, Molecular Biomedical Sciences, North Carolina State University, Raleigh, North Carolina

Erwin G. Pearson, DVM, MS, DACVIM

Professor Emeritus, Department of Clinical Sciences, Oregon State University, Corvallis, Oregon

Konnie H. Plumlee, DVM, MS, DACVIM, DABVT

Laboratory Director, Veterinary Diagnostic Laboratory, Arkansas Livestock and Poultry Commission, Little Rock, Arkansas

Nicola Pusterla, Dr. Med. Vet., Dr. Med. Vet. Habil., DACVIM

Assistant Professor, Department of Medicine and Epidemiology, School of Veterinary Medicine, University of California, Davis, California

Virginia B. Reef, DVM, DACVIM

Professor, Director of Large Animal Cardiology and Ultrasound, Department of Clinical Studies, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

David G. Renter, DVM, PhD

Assistant Professor, Diagnostic Medicine and Pathobiology, College of Veterinary Medicine, Kansas State University, Manhattan, Kansas

Sarah M. Reuss, VMD

Resident in Large Animal Internal Medicine, Department of Large Animal Clinical Sciences, Texas A&M University, College Station, Texas

Steven M. Roberts, DVM, MS, DACVO

Chief of Staff, Animal Eye Center, PC, Loveland, Colorado

Julie Ross, MA, VetMB, MRCVS, DACVIM

Veterinary Surgeon, Centre for Preventive Medicine, Animal Health Trust, Newmarket, Suffolk, United Kingdom

Joan Dean Rowe, DVM, MPVM, PhD

Preface

CONTENT

Large Animal Internal Medicine is an encyclopedic volume for the large-animal veterinarian working with horses, cattle, sheep, or goats. Using the same popular format as the third edition, this edition provides the most current information available by utilizing over 190 experts as authors. This edition contains five entirely new chapters and more than 450 illustrations. Many sections have been strengthened by the addition of outstanding new authors, and chapters have been revised and improved with new references added.

PROBLEM-ORIENTED APPROACH TO DISEASE DIAGNOSIS

The catch-22 of most textbooks is that the clinician must know the diagnosis to locate and read about a specific disease. *Large Animal Internal Medicine* is a multiauthored text that allows the clinician to use the problem-oriented approach to the diagnosis of diseases of horses, cattle, sheep, and goats. Over 130 clinical signs or manifestations of disease are discussed. They are listed alphabetically on pp. 21 and 22; this list can be used to locate a particular manifestation of disease. These same manifestations are listed by organ system at the beginning of Chapter 3 to Chapter14 (Part Two of the book). A favorite feature of the previous editions is the differential diagnosis boxes. We have retained these invaluable diagnostic tools in this edition. Throughout Part Two, complete lists of common, less common, and uncommon diseases associated with manifestations or signs of disease are given in these easy-to-find boxes (see pp. xx to xxi for examples). The clinician is given an approach to each manifestation of disease and a method to work toward a diagnosis. The pathophysiology of a particular manifestation of disease is concisely summarized. Even if a final diagnosis is not reached, the animal with diarrhea, cough, or other problem can be treated symptomatically, a practice that is commonly used in the everyday world.

Similarly, abnormalities in laboratory test results are discussed in Part Four, and complete lists of diseases associated with a given laboratory abnormality are found in easy-to-read boxes (see p. xxi for an example). Interpretation of abnormalities in clinical chemistry, hematology, blood proteins, and clotting tests is made easy. For example, if the problem is elevated serum calcium, the causes of hypercalcemia are discussed concisely, and lists of diseases are given. The clinician can then proceed to a rational approach to the particular laboratory

abnormality. Many readers have found the table for conversion from “American” units to SI units extremely useful.

ORGANIZATION

The basic organization has not changed from the third edition. The book is divided into seven parts:

PART ONE: History, Physical Examination, and Medical Records

PART TWO: Manifestations of Disease

PART THREE: Disorders and Management of the Neonate

PART FOUR: Collection of Samples and Interpretation of Laboratory Tests

PART FIVE: Disorders of the Organ Systems

PART SIX: Preventive and Therapeutic Strategies

PART SEVEN: Congenital, Hereditary, Immunologic, and Toxic Disorders

A detailed discussion of each disease is contained in Parts Five, Six, and Seven of *Large Animal Internal Medicine*. Once the reader has a list of diseases that fit the current problem, specific diseases can be found in these final sections of the book. The organization is that of a traditional disease-oriented text:

Definition and Etiology

Clinical Signs and Differential Diagnosis

Clinical Pathology

Pathophysiology

Epidemiology

Necropsy Findings

Treatment and Prognosis

Prevention and Control

Part Five is organized according to body system and includes internal medicine approaches. Diagnostic tests used in that system are delineated, including ultrasound, endoscopy, radiography, thermography, computed tomography, magnetic resonance imaging, sample collection techniques, electrocardiography, cerebrospinal fluid collection, and biopsy of organs. Numerous illustrations include photographs, ultrasound images, radiographs, electrocardiogram tracings, and endoscopic views. These chapters are written by experts in the field of large animal internal medicine and give details of the most up-to-date treatments available. *Large Animal Internal Medicine* complements existing texts dealing with current therapy.

A neonatal disease section (Part Three), organized by presenting problem, discusses everything from diarrhea to septicemia of foals, calves, lambs, and kids. To aid the clinician in arriving at the proper diagnosis, lists of diseases are given for each manifestation of neonatal disease and are presented in Chapter 19 and Chapter 20, Chapter 51 and Chapter 52 deal with genetic disorders and genetic tests, most of which have only recently been developed. Differences in approach to diagnosis or treatment of neonates and adult animals are cross-referenced throughout the text.

Preventive and Therapeutic Strategies, Part Six, includes chapters with practical information on critical care and fluid therapy, antimicrobial therapy, infection control, prevention and detection of foreign animal diseases, vaccines and vaccination programs, and parasite control programs. Chapter 50 addresses nutrition of the sick animal and gives formulas for both enteral and parenteral support.

POPULAR FEATURES RETAINED

COLOR INSERTS

Chapter 32, Diseases of the Alimentary Tract, has color plates that give endoscopic views of equine alimentary tract disorders. Chapter 39, Diseases of the Eye, contains color plates of ophthalmologic conditions that are best seen in full color.

PRINTED ENDPAPERS

The printed endpapers found in the front and back of the text provide information that is referred to frequently:

Manifestations of Disease

Manifestations of Disease in the Neonate

Clinical Chemistry: Normal Ranges for Large Animals

Normal Values for Erythron Data in Ruminants and the Horse

Normal Values for Leukogram Data (Adult Animals)

Normal Values for Hemostatic Data in Ruminants and the Horse

NEW TO THIS EDITION

NEW TOPICS

The range of new topics is extraordinary. Every chapter has been thoroughly updated. A sampling of new topics includes collection and evaluation of bone marrow, antigen detection tests and PCR, new aspects of critical care, infection control methods for a large animal hospital, prevention, detection, and response to foreign animal diseases, new genetic tests, new tests for *Clostridium difficile,* and new findings on bovine viral diarrhea infection. New ultrasound images are widely used, National Research Council tables have been updated, the neonatal sections are extensively revised, new findings in the etiologies of pinkeye are described, legal requirements for use of pharmaceuticals in food animals, and vaccine advances, advances in treating headshaking in horses, and advances in endocrine and muscle disorders have been added.

INDEX

As a reference, a book is only as good as its index. The index of *Large Animal Internal Medicine* is thorough and extensive, making it an easy-to-use reference to find the answer to any question you may have. The initial page number given is the primary listing.

ACKNOWLEDGMENTS

Many people worked hard to make *Large Animal Internal Medicine* the quality text that it is. More than 190 authors contributed in their area of expertise. Special thanks to Teri Merchant, Shelly Stringer, Sarah Wunderly, Gretchen Van Houten, and all the others at Elsevier who worked so hard on this project. Diana Gomez helped greatly with typing and manuscript preparation, and I am indebted to her.

The motivation for undertaking *Large Animal Internal Medicine* came, in large part, from having been influenced in my professional career by many teachers and colleagues with high standards. In particular I would like to acknowledge Alex Ardans, Humphrey Knight, Martin Drost, and Dick Mansmann. My gratitude to them and respect for them run deep. During my 35 years as a teacher, I had the good fortune of working with many talented, inquisitive, and dedicated colleagues, including Gary Carlson, Ian Mayhew, Lisle George, Sharon Spier, John Madigan, and Bob BonDurant, as well as countless others who helped me. Perhaps the individuals who have the greatest influence on a teacher are the students and residents who through their inquisitiveness keep us interested. Thanks to John House, Gilles Fecteau, Dave Van Metre, John Angelos, Mike McCloskey and all the other great veterinarians I got to work with.

Finally, I would like to acknowledge the love, support, and encouragement of my terrific family: Yibi, Chris, Alex, Bonnie, Kate, and Everett. Family keeps you grounded in reality and tells you when to shut up and sit down!

Causes of Icterus in Horses

LIVER

Common Causes

- Pyrrolizidine alkaloid toxicity
- Serum-associated hepatitis
- Acute hepatitis
- Chronic active hepatitis
- Cholangitis or cholangiohepatitis
- Bile stones, other biliary obstruction
- Fasting hyperbilirubinemia

Less Common Causes

- Aflatoxicosis with liver failure
- Tyzzer's disease (foals)
- Hepatic lipidosis
- Hepatic abscess

Uncommon Causes

- Black disease (infectious necrotic hepatitis)
- Hemangioma, hemangiosarcoma, angiosarcoma

Cardiac neoplasm

Viral arteritis

Gastric or duodenal ulcers

Severe ascarid infection

Lymphosarcoma

HEMOLYTIC ANEMIA

Common Causes

Immune-mediated hemolytic anemia

Ehrlichiosis *(Ehrlichia equi)*

Neonatal isoerythrolysis

Less Common Causes

Piroplasmosis (babesiosis)

Snake bite

Blood transfusion

Erythrocytosis

Uncommon Causes

Equine viral arteritis

Leptospirosis

Bee or wasp sting

Sulfur toxicity

Trichloroethylene-extracted feed

Iron toxicity

Phosphorus toxicity

Herbicide toxicity

Phenothiazine toxicity

White snakeroot poisoning (tremetol)

Onions

Red maple *(Acer rubrum)*

Pentachlorophenol toxicity

Oak toxicity

Mycotoxicosis

Surra, *Trypanosoma evansi* (exotic)

Mal de caderas, *Trypanosoma equinum* (exotic)

Murrina de caderas, *Trypanosoma hippicum* (exotic)

Causes of Icterus in Ruminants

LIVER

Common Causes

Pyrrolizidine alkaloid toxicity

Aflatoxicosis

Fat cow syndrome (fatty liver)

Less Common Causes

Acute hepatitis

Liver flukes

Infectious necrotic hepatitis (black disease)

Liver abscess

Cholangiohepatitis

Uncommon Causes

Sarcocystosis

Hepatic neoplasia

Ruptured gallbladder

Cholelithiasis

Biliary obstruction

Nolina (beargrass) toxicity

Lantana toxicity

Agave toxicity

Wesselsbron disease (exotic) (B, O)

HEMOLYTIC ANEMIA

Common Causes

Leptospirosis

Anaplasmosis

Bacillary hemoglobinuria *(Clostridium hemolyticum)*

Piroplasmosis, babesiosis (exotic)

Less Common Causes

Snake bite

Immune-mediated hemolytic anemia

Transfusion reaction

Postparturient hemolytic anemia

Copper toxicity (especially sheep)

Neonatal isoerythrolysis

Yellow lamb disease (*Clostridium perfringens* type A) (O)

Uncommon Causes

Anaplasma ovis

Eperythrozoonosis

Bee or wasp sting

Brassica species toxicity

Trichloroethylene-extracted feed toxicity

Iron toxicity

Onion poisoning

Zinc poisoning

Phosphorus poisoning

Mercury poisoning

Fireweed *(Kochia scoparia)* poisoning

Mycotic lupinosis

Mycosporum poisoning

Theileriosis (East Coast fever) (exotic)

B, Bovine; *O,* ovine.

Causes of Elevations in Serum Enzymes

ELEVATION OF SDH

Common Causes

Acute liver failure

Liver abscess

Secondary to damaged bowel

Strangulating intestinal lesion

Acute toxic enteritis

Chronic liver failure

Less Common Causes

Acute and severe anemia

General anesthesia

Anoxia

ELEVATION OF GGT

Common Causes

Acute liver failure

Chronic liver failure

Pyrrolizidine alkaloid toxicity

Aflatoxicosis

Cholangiohepatitis

Cholelithiasis

Liver flukes

Uncommon Causes

Higher normal range in young animals

Fatty liver

ELEVATION OF AP

Common Causes

Acute liver failure

Chronic liver failure

Pyrrolizidine alkaloid toxicity

Cholangiohepatitis

Cholelithiasis

Liver flukes

Uncommon Causes

Higher normal range in young animals

Fatty liver

ELEVATION OF CPK

Common Causes

Exertional rhabdomyolysis (azoturia, myositis, tying-up)

Nutritional myodegeneration (selenium, vitamin E deficiency)

Postendurance ride multisystemic disorder

Alert downer cow syndrome (muscle crush syndrome)

Malignant hyperthermia

Malignant edema

Prolonged recumbency with inability to rise

Uncommon Causes

Normal postexercise or postshipping modest increase

Acute cardiomyopathy

Purpura hemorrhagica

Equine influenza

Sarcosporidiosis

Local irritation from intramuscular injections

ELEVATION OF LDH

Common Causes

Muscle Disease

Exertional rhabdomyolysis (azoturia, myositis, tying-up)

Nutritional myodegeneration (selenium, vitamin E deficiency)

Postendurance ride multisystemic disorder

Alert downer cow syndrome (muscle crush syndrome)

Hemolytic anemia

Acute cardiomyopathy

Purpura hemorrhagica

Equine influenza

Sarcosporidiosis

Local irritation from intramuscular injections

Fatty liver

Use of the *Consultant* Diagnostic Database for Development of This Textbook

MAURICE E. WHITE

The writing of each edition of *Large Animal Internal Medicine* has been facilitated by the online diagnostic system *Consultant*.[1] *Consultant* contains information on diseases described in the veterinary literature: 1183 diseases of cattle; 1165 of horses; 808 of sheep; 662 of goats; 606 of pigs; 1491 of dogs; 1046 of cats; and 395 of birds at the time this is being written. For each disease there is a brief description, references, links to the ever-expanding number of online journal articles, and clinical signs that might be seen. Information in *Consultant* is updated daily based on review of periodical literature available online and on paper through the Flower-Sprecher Veterinary Library at Cornell University. *Consultant* is on the Web at http://www.vet.cornell.edu/consultant/consult.asp; in 2006 it received about 1.3 million page views from 380,000 visits.

Two characteristics of *Consultant* are the keys to its use for this textbook. Online editing is rapid, and information from the literature appears in the database quickly; this rapid updating combined with the large number of information sources allows *Consultant* to contain a breadth of up-to-date material that is difficult to find elsewhere, including information on poisonings, rare diseases, or diseases exotic to North America. The second important

factor is the ability of the user to enter a clinical sign or signs (e.g., cough, colic, abortion) for a given species and be presented with a list of diseases for which that sign or signs have been reported.

How was *Consultant* used for development of *Large Animal Internal Medicine?* Much of this textbook is organized by clinical signs. *Consultant* provided a broad overview of possible causes for clinical problems that authors were encouraged to incorporate into their lists of differential diagnoses. Contributors were encouraged to compress, rank, and add to *Consultant*-generated lists on the basis of clinical experience. The use of the database in this fashion facilitated the organization of sign-based chapters.

Consultant and this textbook are symbiotic. The database can be thought of as a generalist that "knows" some up-to-date information on almost every disease in veterinary medicine. Despite that, it remains merely a tool for the clinician who uses it. For example, there are dozens of causes of epistaxis in the horse and it is simple to get a complete list of them and other information from *Consultant*. The clinician must take that list and decide which causes to pursue in an individual patient, in what order, by what means, at what cost, and to what treatment or prognostic end. When tough decisions must be made, expert opinions such as those found in this book are of great help.

We are in the nascent stages of new ways of accessing veterinary information—online journal articles; online textbooks; "distributed" textbooks with reviews by experts on servers throughout the world. As I write this, the website "Veterinary Wiki" has no content and coverage of veterinary topics in Wikipedia is spotty, but growth of the Wiki mode of handling information seems inexorable.[2] In spite of these trends the printed word remains a popular and effective way to capture knowledge. Cooperation such as that between *Consultant* and *Large Animal Internal Medicine* allows practitioners and students to benefit from the linkage between the tireless memory and ease of retrieval of the computer and the convenience of expert knowledge in book form.

1 Chapter 1 Ruminant History, Physical Examination, and Records

Ronald L. Terra

1.1 OBTAINING THE HISTORY

The initial and often the most important step in the diagnostic approach to the sick ruminant is the physical examination. Throughout this process an anamnesis is obtained by asking questions of the owner or manager during the examination of the animal. The examiner should obtain the signalment either by observation or by questioning the owner. The information that one wishes to obtain while taking the history is that related to the chief, or presenting, complaint—that is, the complaint, the duration, whether the onset was gradual or sudden, and any associated signs that have been noted. For females, one must know when the last parturition occurred, and for dairy cows, what the production parameters were in the previous lactation as well as in the current lactation. With dairy cows a drop in milk production is often the only sign noted by the owner. Weight can be either approximated, via heart-girth measurements, or determined exactly if facilities exist to do so. What and how the animal is fed are questions to be asked. Does the animal refuse any or all of the feed offered? Is there more than one ration or feeding regimen for this particular operation? If so, are these same signs noted in animals exposed to different feeding practices? The examiner also obtains vaccination and worming history and inquires about pasture or housing practices to determine the influence that management factors have on the incidence of the disease. Previous diseases noted in the herd, therapeutic regimens used, and resolutions of previous problems are pertinent aspects. Finally, the examiner should note the treatment history of the patient. An example of a history questionnaire that can be used for ruminants is included (Fig. 1-1). Specific problems that are noted in the history or physical examination can be looked up on pp. 21 and 22, and lists of differential diagnoses considered.

1.2 EXAMINATION

A complete examination should always be performed even if the presenting complaint is easily recognizable. The physical examination provides the veterinarian with information that is used to assess the health status of the patient. This information, combined with that obtained while taking the history, enables the practitioner to determine which specific signs of disease are present and often to localize the disease process to specific organ systems. The physical examination also helps to determine which ancillary diagnostic tests must be performed. Additional information gathered during the examination may reveal disorders other than the presenting complaint that warrant further attention and may have a profound influence on the prognosis of the case. Realistically, economic and temporal constraints preclude full examinations in some cases. In these situations the veterinarian must be familiar enough with the complete physical examination to know which aspects can be excluded and which should be performed.

A systematic approach to the animal must be developed and used in every physical examination. The first step is to form an initial overall impression by observing the animal from a distance. The animal is then restrained and examined topographically, beginning on one side, moving to the other, then evaluating the rear and finally the head and neck. Thus individual organs and systems are examined completely, although disjointedly, and the information gained is correlated to form the complete diagnosis.

1.2.1 Visual Examination

As observations are made and a physical examination performed, it is important to follow a systematic approach and to record findings. A checklist has been found to be extremely useful (Fig. 1-2). While observing the animal

from a distance, the examiner should assess its posture, gait, behavior, and physical condition. Observation of the other members of the flock or herd helps to differentiate normal from abnormal characteristics under each particular management system because normal may vary from farm to farm and because what is considered "normal" for a farm by the owner or herdsman might actually be abnormal; this information is valuable for assessing the incidence of a disease or disorder that is caused by management. As more animals in more herds are observed, a background of knowledge is gained that allows the practitioner to assess these management deficiencies more reliably.

The general appearance and conformation of the animal are included in determining posture. These are assessed in light of the age and breed of the patient. Determining abnormalities in posture can be difficult; however, noting these subtle changes can contribute greatly to the diagnosis of a disease process. Conformation is recognized by looking at the overall size and shape with particular regard to height, width, and relationship of the head, neck, and legs to the trunk. The general appearance of the patient in light of overall conformation can then be assessed. Determining a body condition score and correlating it with stage of lactation can offer insight into the course of the presenting complaint. Is the young, growing animal within breed standards for size and weight? (See Chapters 9 and Chapter 13), The condition of the hair coat and presence of external parasites can be noted during the physical examination (e.g., frank hair loss, as seen in louse infestation, or dander and scruffiness of the hair coat, as seen in chronic debilitating diseases).

Fig. 1-1 Example of an initial encounter history form for use in ruminants.

VETERINARY MEDICAL TEACHING HOSPITAL
FOOD ANIMAL
INITIAL ENCOUNTER HISTORY

Observe the animal for signs of abdominal splinting or arching of the back, as can be seen with peritonitis. This posture can also be noted with other disease processes when these produce pain in the ventral abdomen. Lateral curvature of the spine could indicate a congenital defect or a chronic spinal lesion. Carrying the tail up away from the body is seen with conditions resulting in pain or irritation in the perineal region, vagina, or rectum. Standing with all four legs in the classic "saw-horse" stance with the neck and tail held erect is typical of tetanus. Abduction of the elbows is seen in disorders that cause thoracic pain. Lameness can be noted by observing unwillingness to bear weight fully on the affected limb, while either standing or walking. Loss of extensor or flexor capabilities of the joints is seen in nerve paralysis or paresis; it can also be caused by tendon and/or joint contractures, in which case joints are rigid. Walking as if all four feet are sore may indicate laminitis. With bright and alert recumbent animals, a thorough examination to rule out fractures or severe joint trauma is essential. Once these have been ruled out, inability to stand may be indicative of generalized muscular paresis or paralysis. These can be of a primary nature, as with lesions within the spinal column causing cord compression, or secondary to mineral or electrolyte deficiencies (e.g., hypocalcemia, hypomagnesemia, or hypokalemia).

Fig. 1-2 Example of a data sheet for the recording of the pertinent findings from the physical examination.

VETERINARY MEDICAL TEACHING HOSPITAL

FOOD ANIMAL

PHYSICAL EXAM DATA

To be able to judge the behavior of the animal as being normal or abnormal, the observer must call on a large amount of experience. Observing the animal from a distance allows assessment of eating and drinking behavior, as well as assessment of the subject as it is ruminating, urinating, and defecating. How the animal gets up or lies down and how it ambulates are important. Signs indicative of estrus or signs commonly seen with calving might be considered normal or abnormal, given the history and behavior of the animal during these events. Observing the patient during the milking process may also be beneficial. The influence of the manager on animal behavior is very important, as is the overall temperament of the particular breed or herd in question. Normal animals react to the approach of a human being by moving away; however, those that have had extensive contact with people may be more inquisitive. Within a herd one can note animals that are more tolerant than others, more stubborn, more restless, and more anxious. These traits are not necessarily abnormal and need to be differentiated from behavior that would be considered secondary to disease. In general, one must determine whether the behavior is one of a depressed or apathetic animal or of a hyperexcitable or frenzied animal.

Nutritional status and physical condition are assessed by means of observation and palpation. Special attention is paid to the dewlap, the spinous processes of the thoracic and lumbar vertebrae, the shoulder area, and the area around the tailhead. Determination of body condition will then result in a classification of the animal as being anywhere from severely emaciated or cachectic to extremely overconditioned or fat (see Chapter 9 andChapter 13 for body scores). Next it must be determined whether the condition is of a primary or nutritional nature or the result of disease. Disease processes can influence or be influenced by the animal's body condition. Extremely thin animals are seen in primary undernutrition and also with chronic disease. Females carrying multiple fetuses and lactating animals with metabolic abnormalities secondary to abomasal displacements would also show signs of weight loss. Overconditioned animals are at greater risk for a wide variety of disorders primarily related to the accumulation of fat in the liver and excessive fat storage in the omentum.

1.2.2 Physical Examination

With the animal properly restrained, the physical examination can now progress to specific palpation, auscultation, and percussion. Obtaining a sample of urine for urinalysis is of great value if incorporated into the physical examination; it is easy to perform with the use of dipsticks such as N-Multistix. Stroking the perineal region can aid in eliciting urination in the bovine; however, even this is futile if the animal is apprehensive. Consequently, it is recommended that this be done first, while the patient is still fairly relaxed. In the male, elicitation of urination is slightly more difficult and requires massaging of the preputial orifice. Another method is to wash the outside of the prepuce with warm water, but this is less successful. In the female sheep and goat, stroking the perineal area can be attempted, but positive results are rarely achieved. A method that is more reliable but that causes the animal much greater stress is to prevent it from breathing until urination is stimulated. In male or castrated male sheep and goats, gentle massage of the prepuce sometimes results in urination. If that fails, the breath-holding technique can be used. It is recommended that this not be attempted on patients that are severely compromised because of any disease process. (See Chapter 22 for further information on interpretation of the urinalysis.)

Body temperature is then measured with a rectal thermometer. Normal values for each species are given in Table 1-1. There are no absolute values, and the upper and lower limits should be adjusted as necessary to account for ambient temperature and housing. For example, if the ambient temperature is greater than 37.5° C (100° F), a body temperature of 39.5° C (103° F) may still be considered normal for the adult bovine, especially if the animal is not allowed access to shade. When body temperatures approach 41° C (106° F), as a result of very high ambient temperatures, heat stroke may occur. Keep in mind that the animal tries to maintain its body temperature within these normal limits, and marked deviation from the norm would be indicative of a disease process. A markedly

elevated temperature is seen in acute, severe inflammatory processes. Pathologic lowering of the body temperature is seen in disorders that cause an inhibition of metabolism such as postparturient paresis, neonatal hypoglycemia, the end stages of a chronic disease, or severe septicemia resulting from gram-negative bacteria. There is a normal diurnal variation in body temperature of as much as 0.5° to 1° C. In the female there can also be a slight increase in temperature in the days preceding estrus. Neonates are poor thermoregulators and often have a normal body temperature that is 0.5° to 1° C higher than that of adults.

In the evaluation of the thoracic and abdominal cavities, the initial step is the ballottement of the abdomen on the right side. An increase in fluid being sequestered intraabdominally could be related to some degree of intestinal or ruminal stasis or associated with an increase in peritoneal fluid, as with peritonitis or ruptured bladder. Ballottement can also reveal whether any firm mass such as a fetus, impacted abomasum, abscess, or tumor is located in the abdomen. In goats the abdominal fat pad is quite prominent and tends to obscure any significant finding on ballottement. Deep palpation of the paralumbar fossa can sometimes reveal masses in this region, including lymphomas, fat necrosis, or abscesses. In goats, lambs, and calves, two hands are used to deeply palpate the abdomen; the normal freely movable left kidney is usually readily palpable. On the right side an enlarged or painful liver or kidney can be noted. Palpation of an abnormal swelling or firmness, especially with the elicitation of pain, indicates a problem that must be further evaluated.

Table 1-1 Normal Values for Temperature in the Ruminant[1–3]

Animal	Degrees Celsius	Degrees Fahrenheit
CATTLE		
Adult	38–39	100.5–102.5
Calf	39–40.5	101.5–103
SHEEP		
Adult	39–40	102–103.5
Lamb	39.5–40.5	102.5–104
GOAT		
Adult	38.5–39.5	101.5–103.5
Kid	39–40.5	102–104

6

7

The spinal column and ribcage are then palpated; the presence of fractures, enlargement of the costochondral junctions, or the elicitation of pain is noted. Enlargement or fractures of the costochondral junctions are commonly seen in young animals with deficiencies of calcium, copper, or vitamin D.

Auscultation with concurrent percussion by snapping the finger against the thoracic and abdominal walls is the next procedure. Gas trapped within abdominal viscera elicits a “pinging” sound that can be heard with the stethoscope. Localization of these gas pings to certain areas within the abdomen is helpful in determining which alimentary structure is involved (Figs. 1-3 to 1-5). If the cecum is enlarged and gas filled, an abdominal ping can be heard. This can extend caudally to the tuber coxae and cranially through the paralumbar fossa and under the ribcage on the right side (see Fig. 1-3). The diameter of this area can be variable and range from 6 inches (15 cm) in a cecal displacement to 3 feet (1 m) horizontally in cecal torsions. Spiral colon pings are generally localized to the right dorsocranial paralumbar fossa and rarely extend farther forward than the tenth intercostal space. They tend to be round areas 10 inches (25 cm) or less in diameter centered high under the last rib (see Fig. 1-3) and are

commonly found in sick cattle that are anorectic. These pings have no specific diagnostic significance. Gas pings associated with a right-sided displacement or torsion of the abomasum can extend as far cranially as the ninth intercostal space and caudally into the paralumbar fossa (see Fig. 1-4). The diameter of displacements is usually 18 inches (45 cm), whereas that of torsions can be up to 3 feet (1 m). In cases of abomasal volvulus, the animal is usually exhibiting other systemic signs such as increased heart rate, dehydration, depression, scleral injection, and mild colic. In simple right-sided displacements or dilations of the abomasum, the only significant finding may be the small gas ping localized to the abomasum in a cow with depressed appetite and decreased milk production.

Fig. 1-3 Schematic representation of areas of gas pings elicited by percussion of the cecum and spiral colon.

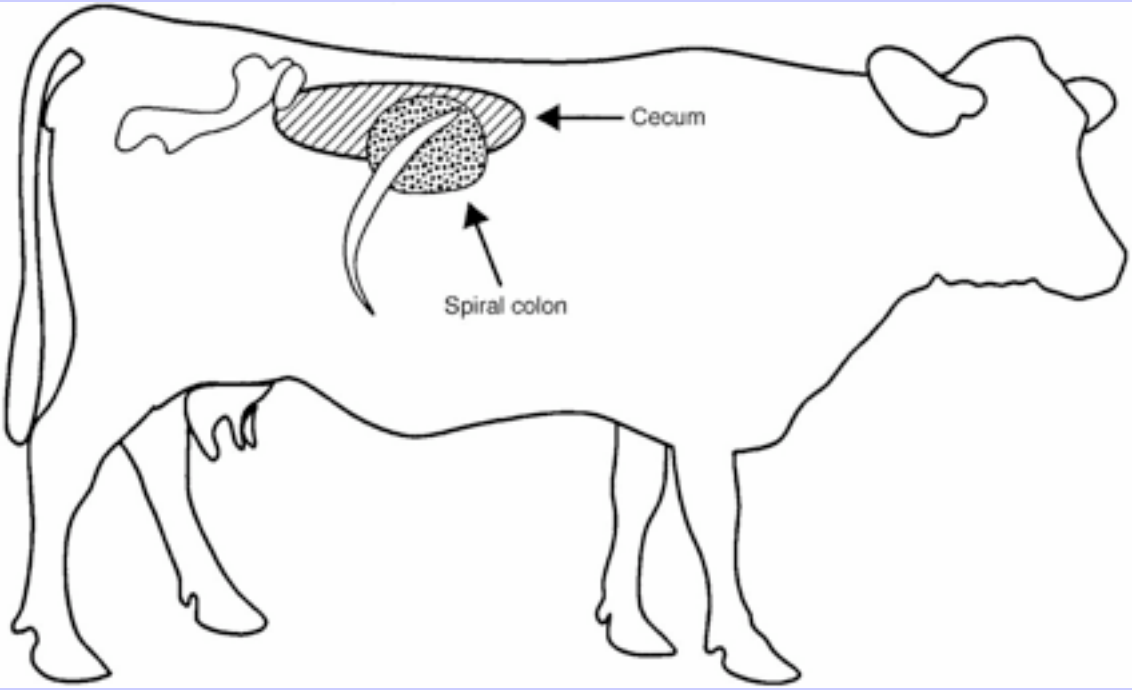

Fig. 1-4 Schematic representation of the area of the gas ping percussed in association with a right displaced abomasum (RDA) or abomasal torsion.

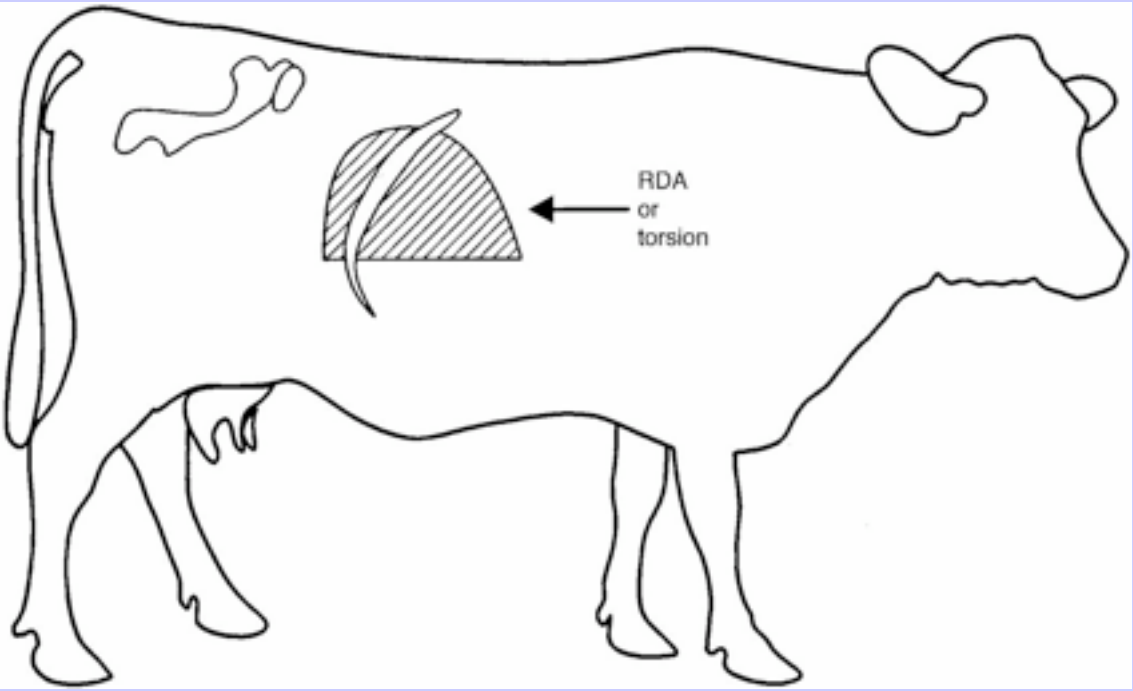

Fig. 1-5 Schematic representation of the area of the gas ping percussed in association with a left displaced abomasum (LDA) or gas ping in the rumen.

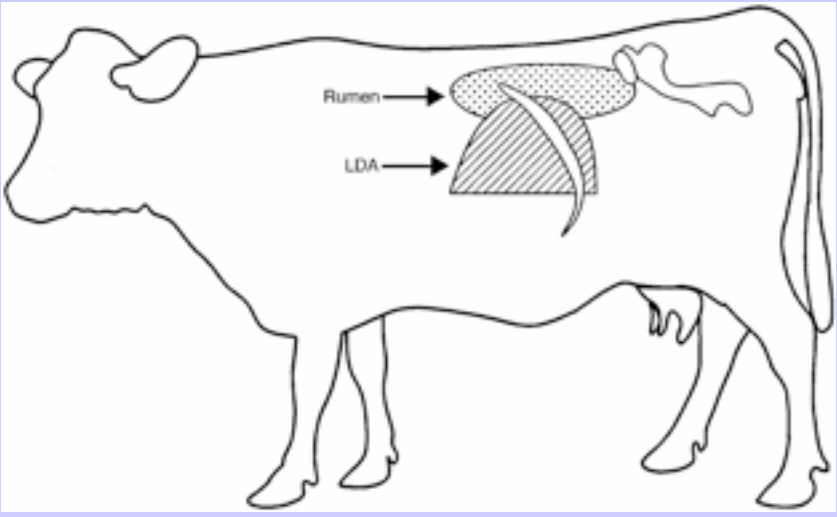

On the left side, gas pings can be noted as originating from the rumen, the peritoneum, or a left displaced abomasum (LDA). The auscultation of a gas ping that is primarily localized to the dorsal aspect of the paralumbar fossa and auscultable on both sides of the spinal column would be indicative of a pneumoperitoneum. The extent of these pings can be from the thoracolumbar junction caudally to the retroperitoneal space. Pings associated with ruminal tympany occupy the whole of the paralumbar fossa and can extend dorsally to the spinal column but generally do not extend over to the right side (see Fig. 1-5). LDA results in a gas ping that is localized, easily outlined, and approximately 12 to 18 inches (30 to 45 cm) in diameter. Caudal extent of the displacement is generally the thirteenth rib; however, it can extend into the paralumbar fossa, in which case the outline of the abomasum can be easily palpated. The LDA should ping over the eleventh rib on a line from the hip to the elbow (see Fig. 1-5). Rumen gas associated with a left-sided ping will rarely ping at this location. Identification of a fluid line within the displacement can aid in diagnosis and is accomplished by ballotting the left paralumbar fossa while auscultating the area of the gas ping concurrently, a process known as *succussion*. LDA often gives a pitch that changes in tone as it is percussed, as a result of movement of the rumen behind the abomasum. Often with LDA, intermittent gas bubbling or "sloshing fluid" sounds are heard. Rumen gas can be further differentiated from gas trapped in an LDA by rectal palpation of the rumen. One can also differentiate rumen gas from that trapped in an LDA by passage of a stomach tube into the rumen. Blowing into the rumen yields obviously auscultable sounds unless an LDA is present, in which case the sounds are muffled as the practitioner listens over the area of the ping. Performing a rumen or abomasal tap, the Liptac test, can further differentiate whether the ping originates from an LDA or the rumen. Fluid collected from an LDA would have a pH of less than 4, whereas that of the rumen should be 6 or higher.

The rumen is examined by both auscultation and palpation. It should have a doughy texture with a small gas cap in its dorsal regions and usually is not distended above a plane formed by the coxofemoral joints. Increased accumulation of gas within the rumen would be seen with acute primary frothy bloat and also with free gas bloat. The rumen contractions should be counted, observed, and auscultated. Normally, primary ruminal contractions occur one and one-half to three times per minute, and the force of the contraction should displace the lateral body wall at least ½ to 1 inch (1 to 2 cm). When auscultated, the ruminal contraction sounds like a dull roar that starts quietly, rises to a peak, and dies away. Hypocalcemia and peritonitis are examples of disorders that result in weak or absent ruminal contractions. Hypermotility is rarely seen but can occur and has been described in association with vagal indigestion.

The cardiac region of the thorax is auscultated next. Heart rate and rhythm are determined at this time. Rate varies among species, and age differences within species are noted. In general, older or larger animals have a slower heart rate. Table 1-2 lists the ranges of heart rate that are considered normal for the ruminant species, depending on age. Tachycardia can be seen in animals that have been stressed or excited, as in the process of restraint. However, with time the rate should return to within a more normal range. Any deviation from the normal heart rate in a quiet, relaxed animal implies a general disturbance of the normal health of the animal. Increased heart rate can be seen with fever, inflammation, pain, hypocalcemia, or metabolic disturbances that result in hypovolemia. Bradycardia is seen with conduction disorders within the heart muscle and with some metabolic disorders (uremia, hypokalemia). The most common causes of arrhythmias are atrial fibrillation in adult cattle and hyperkalemia in diarrhetic neonates. Location and intensity of the heart sounds are also important to note, because muffling or displacement of the sounds can indicate space-occupying lesions within the thorax, pericardium, or mediastinum. With pericardial effusion the heart sounds are initially dull but develop splashy washing machine sounds as a gas-fluid interface develops. This often takes weeks. Normally the heart occupies a space on the ventral thorax between the third and sixth ribs. Most of the heart mass is located on the left side of the chest; thus the heart sounds should be louder on that side. However, if the heart is muffled on the left side and louder than normal on the right, one should consider the possibility of inflammation of the pericardium or lung lobes on the

left side of the chest. Displacements of the heart sounds caudally are an indication of a space-occupying lesion in the anterior thorax or mediastinum, such as an abscess or neoplasm. Cranial displacements of the heart sounds would be noted with distention of the ruminoreticulum, eventration of abdominal viscera into the thorax through a diaphragmatic hernia, or other space-occupying lesions as noted previously. If any murmurs are noted on auscultation, an attempt should be made to localize the murmur to a specific heart valve. While the heart is auscultated, the pulse should also be palpated. The easiest point to fine a pulse while the heart is being auscultated is at the vascular notch of the mandible where the facial artery is easily palpated. Pulse deficits in conjunction with an increase in heart rate are seen in arterial fibrillation and premature ventricular contractions. The heart rhythm is also noted. Dropped beats, gallop rhythm, and sinus arrhythmias should be compared with other clinical signs to determine importance.

Table 1-2 Normal Resting Heart Rates (Beats/Min) for Adult and Young (<30 Days of Age) Ruminants[1–3]

Animal	Average	Range
CATTLE		
Adult	60	40–80
Calf	120	100–140
SHEEP		
Adult	75	60–120
Lamb	140	120–160
GOAT		
Adult	85	70–110
Kid	140	120–160

The prefemoral and prescapular lymph nodes are palpated. Enlargements would be seen with inflammatory processes occurring in the regions that they drain. The skin is then palpated, starting along the top line and moving down over the abdominal and chest walls to the ventral midline. The presence of subcutaneous gas or edema is noted, as is any elicitation of pain. Emphysema can have iatrogenic causes (e.g., be secondary to abdominal surgery) or result from pulmonary alveolar rupture, gas gangrene, or puncture wounds. Edema, if noted, is usually ventral and is the result of lowered plasma oncotic pressure or increased venous pressure. Right-sided heart failure, as seen in traumatic retic-ulopericarditis, pericarditis, mediastinal masses, or severe pulmonary disease, results in increased venous pressure. If this is the case, a distention of the jugular veins with jugular pulse should also be evident. Protein-losing enteropathies or nephropathies are causes of lowered oncotic pressure, as is liver failure, which results in a lack of synthesis of plasma proteins. Fluid and gas from subcutaneous injection of large volumes of medications such as calcium gluconate can sometimes be confusing.

The thorax is then auscultated and percussed. Respiratory rate (Table 1-3) and pattern are determined at this time, and the lungs are auscultated. If increased inspiratory or expiratory effort is noted, it should be correlated with auscultatory and percussive findings in an effort to determine lung pathology. Normal ruminant lung sounds vary greatly among species. In calves, sheep, and goats the relatively thin chest wall allows one to hear inspiratory sounds ventrally and over the large airways, whereas expiratory sounds are minimal (except in sheep, where they are frequently audible because of the large amount of mucus in sheep airways). In larger cattle, only very faint

inspiratory sounds are normally heard. Lung sounds can be classified as normal or harsh (tubular) or as wheezes or crackles. These sounds can vary over the different areas of the thorax or can be found singularly over the entire lung field. Significant pulmonary pathology may be present in ruminants *without* any auscultable abnormalities. Total absence of lung sounds ventrally indicates pleural effusion or pulmonary abscessation with loss of airways. When ventral consolidation of the lung occurs, airway sounds are transmitted well and easily heard ventrally as pipestem sounds similar to those heard over the trachea, whereas percussion reveals a marked increase in ventral lung density. The trachea should also be auscultated. Inspiratory dyspnea and stridor are usually the result of extrathoracic obstructions to airflow (nose, pharynx, larynx, extrathorac-ic trachea). Pneumothorax can also result in loss of auscult-able airway sounds, which may be absent dorsally or entirely over the entire side if the lung has collapsed completely.

Table 1-3 Normal Resting Respiratory Rates (Breaths/Min) for Adult and Young Ruminants[1–3]

Animal	Average	Range
CATTLE		
Adult	24	12–36
Calf	48	30–60
SHEEP		
Adult	36	12–72
Lamb	50	30–70
GOAT		
Adult	28	15–40
Kid	50	40–65

Place the middle finger in the intercostal space and slap the finger with the opposite hand or use a tablespoon and rubber hammer to accomplish percussion of the chest wall to determine the ventral lung border. Percussion is most useful in goats and calves. In sheep the wool precludes effective use of the technique, and in adult cattle the chest wall is often too thick to effectively evaluate changes in percussion tones. The chest is percussed in a dorsal-to-ventral direction, moving caudal to cranial on the chest wall. A change in resonance is noted when the ventral border is reached; a line demarcating this change in resonance is the junction of the diaphragm to the thoracic wall. In the ruminant this line should be described by joining a point at the junction of the eleventh rib and the epaxial musculature dorsally to a point at the middle of the ninth rib, then cranially to the point of the olecranon. The cranioventral portion of the percussed thorax is dull because of the heart field (approximately 3 inches [7.5 cm] above the olecranon in adult cattle; 1 to 2 inches [2.5 to 5 cm] in calves, sheep, and goats). Finding an increased area of dullness in the cranioventral lung field associated with harsh lung sounds would be an indication of lung consolidation as seen in *Pasteurella* pneumonia. Pulmonary emphysema (atypical interstitial pneumonia) should be considered when the lung field is larger than expected, the animal is dyspneic, and airway sounds are minimal. A ventral border that is markedly elevated and in a straight line could be an indication of pleural effusion. In this case auscultation would reveal decreased lung sounds ventrally and possibly the presence of pleural friction rubs. Acoustic percussion of the lung field can extend into the chest only to a depth of 2 to 2½ inches (5 to 6 cm). Lesions within the thoracic cavity that lie deep-er than this cannot be percussed.

9

10

The next step in the physical examination is to assess for evidence of pain in the ventral portion of the abdomen and thorax. This can be accomplished through the use of the withers pinch test or by ballottement of the xiphoid region. The withers pinch test involves auscultating the trachea while the withers are simultaneously squeezed and pushed ventrally. Painful lesions result in the ruminant resisting normal ventral movement of the spine and/or emitting a grunt or holding its breath when this test is performed. Ballottement of the xiphoid is also done while the trachea is auscultated. The xiphoid region is pushed with a knee or struck with a closed fist, and an elicitation of a grunt would indicate pain in this region. The examiner can then ballotte the remainder of the ventral abdomen and thorax to classify the lesion as localized or diffuse. If localized, the region affected should be identified. It should be noted that the animal may kick the examiner during the xiphoid ballottement test; thus proper precautions should be taken.

The subcutaneous abdominal veins are assessed next and palpated along their length for the presence of thickened walls, distention, or pulses. Distention and pulses may be abnormal if they correlate with other clinical evidence of right-sided heart failure. Thickening of the wall or evidence of thrombosis is often a consequence of faulty intravenous injection of irritating substances or of injuries that result in hematomas or abscesses.

If the animal is lame or has postural abnormalities, the feet and legs are palpated next. If the animal is uncooperative, it may be necessary to sedate and/or cast it. If sedation is necessary, it should be performed at the end of the physical examination. Care should be exercised for obvious reasons. The examination consists of comparing one foreleg with the other then comparing both with the expected norm. The same procedure is followed for the hind legs. Abnormalities in the shape of the claw may be hereditary or may be caused by nutritional deficiencies, poor leg conformation, poor housing, or as a sequela to laminitis. The coronary bands should be palpated for evidence of pain or increased heat. An attempt should be made to pick up all four feet individually and observe the soles and interdigital regions for necrotic areas, areas of bruising or swelling, draining tracts, or presence of foreign bodies. The fetlock, carpal and tarsal, stifle, and elbow joints are all easily accessible and should be examined for swelling, tenderness, edema, heat, instability, and crepitation. Each joint should be tested over its full range of motion, and any elicitation of pain should be noted. Physical findings should be consolidated into a decision as to whether the joint problems are infectious or traumatic. Sheep or goats with acute polyarthritis most commonly have mycoplasma or chlamydial infection. Chronic joint pain in goats (often with soft-tissue thickening and enlargement caused by synovitis) is frequently attributable to caprine arthritis encephalomyelitis. Conformation of the legs should be analyzed because this could contribute to a joint or foot problem. The pelvic girdle does not lend itself to extensive examination; however, one can note symmetry or asymmetry and further evaluate during the rectal examination. Fractures of the tuber coxae, subluxation of the sacroiliac junction, acetabular fractures, fractures of the head or neck of the femur, and dislocation of the coxofemoral joint may all be diagnosed by evidence gained during palpation and observation of the pelvic area. The dislocated or fractured limb is frequently shorter than the normal opposite limb. The tail can also be examined for evidence of fractures, paresis, or paralysis.

The perineal region is examined by noting the external condition of the genitals and rectum. Anal sphincter tone can be assessed, and the presence of vaginal discharge can be noted. In males the testicles, spermatic cord, and epididymis should be palpated for the presence of nodules or areas of fibrosis. The testicular circumference can be measured and compared with what is expected for age and breed. These measurements are noted in Tables 1-4 and 1-5. The perineal part of the penis can be palpated for the presence of hematoma or swelling and pain (cellulitis or abscess). In the female the supramammary lymph nodes can be felt at the attachment of the udder to the perineum. Enlargement of these nodes occurs with mastitis or lymphosarcoma. The udder is palpated for the presence of fibrotic areas, commonly seen secondary to staphylococcal mastitis or associated with *Arcanobacterium (Actinomyces) pyogenes* abscesses. The presence of a swollen quarter or quarters with pain and

heat may be associated with mastitis caused by gram-negative bacteria. Cold damp areas of skin on the udder that are discolored, necrotic, and possibly sloughing are evidence of gangrenous mastitis. In lactating animals, milk should be present in each quarter, and some of this milk should be expressed for examination. The milk should be of normal color and consistency and should not have any appreciable smell. The presence of leukocytic flakes or clots (garget) is an indication that the udder is mounting an inflammatory response. This response can be measured qualitatively by using the California Mastitis Test (CMT). One should also collect individual quarter samples from those quarters showing garget or those that test positive on the CMT for bacterial culture and sensitivity.

The next step is to evaluate the head and neck regions. The head should be symmetric in appearance, and any asymmetry should be evaluated to determine whether the deviation is caused by a neuromuscular or a skeletal defect. Facial nerve paralysis results in one type of asymmetry, whereas a frontal sinusitis with concurrent displacement of the frontal bone appears differently. Discharges from the eyes, ears, nose, or mouth are noted and correlated with other physical findings. The oral cavity is examined by grasping the tongue with the hand and extending it out through the interdental space. Muscular tone of the tongue is evaluated at this time. The normal animal will resist extraction of the tongue and will quickly retract the tongue into the oral cavity when released. Increased ease of extraction and delayed retraction are indicative of diseases resulting in flaccid paralysis or paresis of skeletal muscle, such as seen in botulism, for example. The tongue and oral mucosa are examined for the presence of erosions, ulcerations, foreign bodies, or areas of necrosis. The dental arcade is evaluated for age of animal, absence of teeth, loose teeth, or necrotizing gingivitis. The color of the mucous membranes is noted. Icterus, pallor, hyperemia, cyanosis, excessive reddening, or brown “mud-colored” mucous membranes can all be noted, depending on the underlying disorder. Mucous membrane color is best evaluated in the eyes and/or vulva because of the presence of pigments in the oral mucosa of many ruminants. The smell of the breath is noted and, if fetid, might be an indication of a retropharyngeal abscess caused by trauma, lung abscess, or gangrenous pneumonia. If the breath is foul, deep palpation within the oral cavity for an abscess or necrotic area is indicated.

Table 1-4 Expected Values for the Scrotal Circumference of the Bull at Different Ages[4]

Age (Months)	Scrotal Circumference (cm)
12–14	30–34
15–20	31–36
21–30	32–38
31	34–39

Table 1-5 Expected Values for the Scrotal Circumference of the Ram at Different Body Weights[5]

Body Weight (kg)	Scrotal Circumference (cm)
<45	23–27
45–70	27–33
70–90	30–36
90–115	31–37
115–135	33–38
135–160	36–40

The mucous membranes of the nares are examined, and erosions and ulcerations are noted. Nasal discharges can be an indication of a pulmonic problem but can also be seen with sinusitis. Bilateral discharge is most commonly associated with pneumonia, and unilateral discharge is more often an indication of a sinus problem. However, percussion of the sinuses is necessary to fully evaluate the presence of a discharge. Normal sinuses percuss with a hollow sound, much like that of a hollow tree, and dullness on percussion might indicate sinusitis, sinus cyst, or other fluid or mass in the sinus.

The eyes are examined next. The sclera and mucous membranes are evaluated in much the same manner as the oral and nasal mucous membranes. The corneas are examined for the presence of opacities, discolorations, ulcerations, and lacerations. The position and size of the corneal opacities or ulcerations can be helpful in determining the cause. Foreign bodies such as plant awns and seeds beneath the third eyelid often cause opacity of the medial aspect of the cornea. Infectious bovine keratoconjunctivitis (pinkeye) is usually localized to the central cornea and causes severe corneal ulceration. When the mucosal diseases cause corneal opacities, they generally do so at the junction of the cornea and sclera and usually do not ulcerate the cornea. The anterior chamber should be examined for the presence of hyphema or hypopyon. These can sometimes be seen in animals with severe bacteremia, especially in neonates with failure of passive transfer. The animal should be evaluated for the presence of a menace reflex (absent in normal neonates for up to 2 weeks), and the pupillary light responses should be observed. Nystagmus and strabismus should be characterized, if present, because the direction is important in localizing the lesion. Nystagmus or strabismus or a deficit noted in the pupillary light reflex or menace reflex is indicative of underlying neurologic or ophthalmologic disease.

The ears should be palpated and evaluated as to their temperature and the presence of skin lesions. They should be warm to the touch. Ears that are cold are an indication that there is decreased blood flow to the periphery, as seen in hypocalcemic states, with decreased cardiac output, or in severe toxic states caused by peripheral vasoconstriction. The presence of small crusty areas or erosions of the skin of the pinna is seen in some of the mucosal diseases such as bluetongue or bovine virus diarrhea. In sheep with acute bluetongue, edema of the face and ears sometimes occurs. If aural discharge or head tilt is present, the ear canal should be examined grossly and with the use of an otoscope for the presence of foreign body or parasites. Purulent discharge can be noted and is an indication of otitis externa. Noting that the eardrum has ruptured along with the purulent discharge is diagnostic of otitis media (and possibly otitis interna). Animals that have suffered trauma to the laryngeal or throat latch region and have a basisphenoid fracture can have bloody discharge from the aural canal. Correlation of the otoscopic findings with other clinical findings is necessary to arrive at a definitive diagnosis.

The palpable lymph nodes of the head and neck include the parotid, the submandibular, and the deep retropharyngeal. The deep retropharyngeals can be palpated externally, if enlarged, in the sheep, goat, and calf. They can be examined in the adult bovine by extending the hand through the mouth and palpating the pharynx. By keeping the animal's mouth open with one hand and guiding the other hand along the dorsum of the tongue to its base, the examiner can then extend the hand aborally into the pharynx. Enlargements of the deep retropharyngeals, abscesses, or other masses can then be palpated. The most common causes of masses or abscesses in the pharyngeal region are infectious or iatrogenic (e.g., secondary to trauma from a balling gun, paste wormer gun, or other instrument). The submandibular nodes are located in the intermandibular space and are identified by slipping the skin and underlying tissue through the fingers. These nodes are oval and about the size of a walnut, or 1 to 2 inches in diameter (2.5 to 5 cm). The parotid lymph nodes are almond shaped and are located just caudal to the ramus of the mandible and about 4 inches (10 cm) ventral to the ear.

The skin of the neck is palpated, with attention paid to the presence of abscesses, lacerations, or other lesions. Skin turgor can be assessed by tenting the skin and measuring the time it takes for the skin to return to normal shape. This is used to determine the state of hydration. In normal, hydrated animals the skin returns to normal position within 1 second. Using other factors such as sunken eyes, dryness of mucous membranes, abnormal heart rate, and degree of illness, an estimation of percent dehydration is made. Dehydration is first noted clinically when the animal is approximately 5% dehydrated, and death occurs at 12% to 15% dehydration.

The larynx should be palpated for enlargement and the presence of pain. The trachea should also be palpated for the presence of fractured tracheal rings, collapsed areas, and pain on palpation. The jugular veins are examined for the presence of distention and pulses. Thrombosed veins should also be noted because this condition may alter the desired course of therapy and often prevents placement of a catheter. The venous stasis test is performed on the jugular by holding off the vein in the midcervical region. Normally the vessel fills above the point of occlusion and remains collapsed below. With restricted venous blood flow, as seen in cases of right-sided heart failure, a positive stasis test can result. In these cases the vessel below the occluded point fails to collapse or takes a prolonged time to do so, and a jugular pulse is frequently present.

The final step in the physical examination is rectal palpation. This cannot be accomplished in small ruminants, so this section is directed primarily toward the bovine. The pelvic area is evaluated for the presence of retroperitoneal abscesses or fractures of the pelvic bones. The left kidney can be palpated for overall size and shape, which is normally lobulated in cattle, and the kidney can be gently squeezed to determine if pain is evident. The rumen should be palpated and the findings compared with those noted on percussion and auscultation. If there is any evidence of intraabdominal gas pings, an attempt should be made to palpate the suspected organ. This can provide information that may be helpful in determining therapeutic or diagnostic directions. The rectal palpation can reveal the presence of masses that were not palpable externally, such as fat necrosis or tumors. Adhesions and evidence of peritonitis can also be palpated rectally, and attempts should be made to localize them to a specific area of the abdomen to establish potential cause. The preiliac (or internal iliac) lymph nodes are located by sweeping the hand along the craniodorsal face of the ilium. These nodes normally have the size and shape of a walnut. Enlargements are noted with lymphosarcoma, peritonitis, and severe limb inflammation. The lymph nodes of the aortic bifurcation are very small and not easily palpated. Their ability to be palpated would be evidence of abnormal enlargement. Palpation of the genital tract is directed toward establishing size, shape, and presence of abnormalities. These contents could be normal, as with a pregnant animal bearing a fetus, or abnormal, as seen with a pyometra. If it is determined that a cow is not pregnant, the ovaries and oviducts should be palpated for structures and abnormalities. In the bull, particular attention should be paid to the prostate, seminal vesicles, and bulbourethral gland.

Diagnostic imaging using an ultrasound probe in conjunction with rectal palpation can add to the information already gathered during the physical examination to further refine the problem and aid in prognostication and development of the therapeutic plan. Proper manipulation of the probe can allow for imaging the kidney, the uterus, the bladder, and the rumen wall. Abnormal structures noted on palpation of the abdominal cavity can also be imaged. The accessory sex glands in the male can be visualized also.

1.3 MEDICAL RECORD

The information gathered by means of the physical examination (see Fig. 1-2) is compiled and correlated with the data obtained during the history (see Fig. 1-1). A problem list should be formulated through the physical examination and anamnesis, leading to the development of a specific diagnostic plan, diagnostic ruleouts, and a proposed course of therapy (Fig. 1-6). Prognosis can also be assessed with the information now in the examiner's hands. Accurate recording of the abnormalities noted during the examination should become part of the medical record and can prove valuable in following the course of the case. In addition, with each complete and accurate physical examination performed, the practitioner becomes more skilled in the procedure, adapting it to fit his or her needs, and using his or her time more efficiently. With the number of diagnostic tests available to the profession today, the information gained from the physical examination will allow the examiner to pick the tests that are specific for those disorders suspected, which saves the practitioner time and the client money.

1.4 DIAGNOSTIC TESTS THAT CAN BE APPLIED IN THE FIELD

There are laboratory procedures that can be performed in the field, the results of which would prove beneficial in the development of a diagnostic plan. These include the CMT, partial urinalysis (dipsticks), ruminal pH determination, and milk or blood progesterone tests. In addition, some serum chemistries can be performed cowside with the use of the i-Stat.*

The CMT is a simple procedure that aids in the detection of clinical or subclinical mastitis (see Chapter 36). This procedure is done routinely during all physical examinations of lactating cows. Partial urinalysis is accomplished by collecting the urine and using any one of a number of urine dipsticks that can be commercially obtained. With a suspected case of lactic acidosis, a rumen sample can be collected through the stomach tube or via percutaneous needle puncture, and rumen pH can be determined. Most drugstores carry pH paper that can be used for this procedure. Be certain that the paper has a standard range, because there are papers that are specific for the acidic or the alkaline range. A rumen pH below 4.5 would be indicative of lactic acidosis. Numerous cowside progesterone assays that use either milk or blood as substrate have recently been developed. These can be relatively easy to use and interpret or they can be difficult, so discretion should be used when making initial purchases. These ancillary diagnostic procedures are explained in greater detail later in this text.

1.5 INSURANCE, INTERSTATE, AND PREPURCHASE HEALTH EXAMINATIONS

The complete physical examination as described in the preceding sections is necessary for a proper prepurchase or insurance examination. For insurance purposes a more complete accounting of the examination must be done. This means that all findings, whether normal or abnormal, have to be recorded. A specific form is generally provided by the insuring agent, and this should be used. Potential for future legal action also exists whenever an animal is insured; therefore it is in the practitioner's best interest to complete the insurance form accurately.

The prepurchase examination is similar to the insurance examination. The physical examination form (see Fig. 1-2) can be used to record findings. The prepurchase examination could be performed on the highly pedigreed female that is being consigned to sale, but it is more often performed on the male scheduled for use as an artificial insemination stud. Occasionally one could be asked to examine an animal under consideration for purchase. Experience indicates that the veterinarian should be employed by the potential buyer in these cases. This arrangement avoids any potential accusations of conflict of interest on the part of the examining veterinarian. A complete blood count and a chemistry panel should be run. Generally it is prudent to certify that the animal is healthy and to test for tuberculosis, brucellosis, and bovine leukosis (using agar gel immunodiffusion). Additional laboratory tests for anaplasmosis and bluetongue may be indicated. Often an animal being consigned to sale or one going into artificial insemination service is required to meet federal regulations for interstate shipment. This information can be obtained from the federal veterinarian in charge in your area or from the office of the state veterinarian in the state of destination.

A problem arises when the number of animals submitted for interstate health examination is large. Economic and temporal constraints usually preclude complete examination of all the animals presented. At such times the visual examination described earlier can prove helpful in determining which animals are to be singled out for the more complete physical examination. The examination of individuals is less complete than for prepurchase or insurance examinations, because such factors as fertility are not at issue when filling out an interstate health certificate. Choosing animals with abnormalities in behavior, physical condition, gait, or posture allows the practitioner to concentrate on those that have the most potential to be diseased. Also, one can be fairly confident that if all the animals appear normal on the general examination, they are healthy and would be suitable for interstate shipment as long as the results of the intradermal tuberculosis test and required serologic tests prove negative. To sign an interstate health certificate, a veterinarian must be accredited and licensed in a state. It is essential that a veterinarian signing an interstate health certificate have examined the livestock sufficiently and diligently enough to be confident that no infectious or contagious diseases are present in the consigned group. A call should be placed to the office of the state veterinarian in the state of destination to be sure that all current requirements are fulfilled before shipment is scheduled.

2 Chapter 2 Equine History, Physical Examination, and Records

Kathleen Casey Gonda

T. Douglas Byars

The ideal purpose of the physical examination is to determine what or if a problem exists. The results should be used to establish a diagnostic plan, prepare a therapeutic approach, and develop a prognosis.

The nature of an internal medicine problem does not always allow for each objective of the physical examination to spontaneously or quickly generate either a diagnosis or a prognosis. More realistically, the examination process dictates the specific laboratory tests or procedures to be performed that support the diagnostic or therapeutic effort. The clinician's self-discipline regarding the extent of the physical examination should be guided by experience, efficiency of time, and the ancillary diagnostic aids that are available. A complete and extensive examination of each patient may not always be practical, especially in busy private or academic practice situations. In these cases the clinician should provide for the client's concerns with an expedient history and a pertinent physical examination process that addresses the client's complaint (e.g., a rectal examination is not required for an evaluation of a pneumonia patient).

2.1 PHYSICAL EXAMINATION RECORD

Preparation for the initial contact time with the client and patient should begin with a system of record keeping. Ambulatory records are usually more flexible than “in-house” hospital admission forms. Both field and clinic forms should include designated spaces for the client or agent's address and phone number. An area for the complete signalment (name, sex, breed, color, age), including an estimated weight, should be provided. If the patient is unnamed, as with foals, it should be listed in the dam's name with the year of birth (e.g., Curious' 06). The sire's name should not be used because more than one foal per year would be expected from a stallion's crop. Whenever surrogate mares produce multiple foals from a single embryo transfer dam, a new system of naming and identification will have to be incorporated. Additional identification of the patient may include a lip tattoo, freeze brand, or microchip number and if available should be noted in the horse's record. By 2009 the federal government will have in place a system that uses microchip technology to permanently identify and track the movement of all species of livestock, including Equidae. In the event of a disease outbreak, rapid identification and surveillance of affected or exposed individuals will be possible. The National Animal Identification System (NAIS) will allow all livestock owners, including hobbyists, to enroll and participate in this program.[1]

2.2 EQUINE INSURANCE

If the animal is insured, this should be documented, preferably with the insurer's telephone number. In addition, the type of insurance should be noted (e.g., mortality and/or surgical and medical). It is the client's or his or her agent's responsibility to notify the insurance company representative whenever an animal insured for full mortality contracts an illness or sustains an insult, life-threatening or not, that requires a veterinary examination. If the patient is insured, it is considered a professional courtesy for the veterinarian to also communicate directly with the insurance company, especially with a life-threatening illness. Also, permission from the insurance company is required whenever a general anesthetic, surgical procedure, or euthanasia is to be performed. Whenever euthanasia is requested, the insurance company may require a second opinion from an adjusting veterinarian. If a direct representative from the insurance company cannot be contacted immediately, the clinician must exercise professional judgment in assuming the responsibility for a humane or critical decision. The client or agent should be

in agreement with the decision, and all communications and pertinent data should be documented in the medical record. If a necropsy is to be performed, it should preferably be in the presence of another veterinarian from a different practice. The American Association of Equine Practitioners (AAEP) provides an insurance pamphlet as a guide to veterinarians.[2] Table 2-1 is an abbreviated list of the types of equine insurance offered.[3]

2.3 HISTORY

The medical history should be directed to the clinical problem. The "herd health" of the stable or farm is briefly depicted by the vaccination and parasite control program. The diet should be determined, including supplements, the grazing environment, stall or housing schedule, and the medical problems concerning other animals on the premises that may coincide with a group incidence of the client's complaint.

When a veterinarian is dealing with neonates, the reproductive and foaling history of the mare is important in establishing an early diagnosis. Any compromise to the mare's gestation (e.g., systemic disease, general anesthesia, or administration of certain medications), foaling, or lactation; placental abnormalities; and any problems that occurred during previous pregnancies should be questioned and considered to be important, pertinent historical data.

A description of the types of medication used before hospitalization may aid in determining if "masking" agents have inadvertently been used. Tranquilizers or sedatives are frequently used for vanning and shipping purposes, and in many instances a van driver or hauler is unaware of medications used or the patient's medical condition. Analgesics such as flunixin meglumine, which are often inappropriately administered by owners or farm staff, may mask signs of pain or colic and alter interpretation of the severity of the horse's condition on arrival. These drugs can cause confounding clinical signs of hypotension, bradycardia, lethargy, weakness, and ataxia. Failure of such an analgesic to abolish clinical signs may necessitate hospital or clinic admission for further evaluation or surgical consultation. Conversely, the failure of other previous medical treatments can aid in the initial selection of more appropriate therapeutic planning.

15

16

Table 2-1 Equine Insurance

Type of Insurance*	Coverage	Role of Attending Veterinarian
Perils	Covers mortality claims for shipping accidents, fire, and natural disasters such as lightning	Inform clients of responsibility to inform insurance company
Mortality†	Covers mortality claims for all life-threatening conditions (e.g., colics)	Inform clients of responsibility to inform insurance company of any anesthetic, surgical needs, or euthanasia
Use	Covers a loss in intended use (e.g., racing, fertility)	Inform clients of responsibility to inform insurance company of any anesthetic, surgical needs, or euthanasia
Major medical or surgical	Covers payment of medical or surgical costs with set limits based on policy	Inform clients of responsibility to inform insurance company before procedures Supply estimate of cost to client Policy is in addition to mortality coverage

* The client is responsible for the costs of veterinary care and treatment unless a medical and surgical policy exists.

† Fetal mortality insurance covers unborn foals, usually until 24 hours after birth.

The patient's individual problems should be determined according to such factors as clinical history of onset, feed and water consumption, fevers, and decrease in performance. In essence, the clinician must effectively “zero in” on the problems at hand.

2.4 PHYSICAL EXAMINATION

The extent of the physical examination will be subject to the environment where the examination is conducted (field vs. hospital), the equipment at hand, and the ancillary personnel available for restraint and procedural purposes. In a hospital setting the clinician should have immediate access to most of the equipment and diagnostic instrumentation listed in Box 2-1. The physical examination sheet should provide a systematic list of the organ systems being evaluated. Vital signs (temperature, pulse, and respiratory rate) should be documented in the “calm” animal, if possible. Abnormal findings are described in an appropriate space provided, usually below the body systems checklist. Using the same numeral for each body system throughout the examination process and in problem identification is useful for future caseload recall, especially if a computer is used and codes can be applied to clinical findings and diagnosis. At the completion of the physical examination, the major problems identified are listed, and appropriate laboratory tests can be requested. The final diagnosis is seldom determined at the time of the initial examination. The final diagnosis represents the final assessment and should be filled in at the appropriate time (e.g., hospital discharge).

A general evaluation of the equine patient should be made from afar. This is particularly important for neonates at the side of their dams. The initial observations of body condition, posture, weakness, lethargy, incoordination, lameness, and musculoskeletal asymmetry are more easily observed a slight distance away from the patient.

2.4.1 Box 2-1 Recommended Examination Room Equipment and Ancillary Services

2.4.1.1 EXAMINATION ROOM EQUIPMENT

Records (examination sheet and request forms)

Thermometer

Clock with second hand

Stethoscope

Twitch

Nasogastric tube

Hoof knife and testers

Ophthalmoscope

Otoscope

Endoscope

Electrocardiogram (ECG) machine

Ultrasound (linear or sector scanner)*

Sphygmomanometer and Doppler ultrasound scanner (tail or limb)

2.4.1.2

ANCILLARY SERVICES

Radiology and imaging services

Ultrasound consultation

Laboratory services including point-of-care diagnostics

* The ultrasound service is more appropriately located in the examination room rather than as a consultation service.

The integumentary system can usually be quickly evaluated as to the type, distribution, and number of lesions and site and layer of involvement—for example, 3 × 6 × 2 cm raised, nodular, nonpainful mass involving the cutis and subcutis. Such a lesion would be readily available for superficial evaluation. However, subtle lesions of petechia and ecchymosis cannot be visualized in the integument because the hair coat and pigment hide lesions that are obvious in other species, such as purpura of nonpigmented humans and pigs. In these instances the mucous membranes must be examined as an extension of the integumentary system. If obvious multiple lesions of the skin are present, documentation is usually expedited by drawing a picture of a horse and indicating the distribution in the drawing, including both sides of the horse (see Skin Disease Examination, Chapter 11). Gross generalized distortions (e.g., anasarca) may be viewed as lesions of possibly more than one body system (integumentary and circulatory).

16

17

For the internist, evaluation of the musculoskeletal system usually involves a rudimentary examination of the site and appearance of the disease processes. Primary lameness is more commonly evaluated by clinicians familiar with diagnostic nerve blocks, arthrocentesis methods (e.g., septic arthritis in foals), and radiographic findings. It should be noted, however, that acute (caused by fracture) or chronic lameness can coexist with primary neurologic disorders (e.g., equine protozoal myeloencephalitis). Therefore, when warranted, the patient should receive a cursory neurologic evaluation (see Chapter 8) in conjunction with the musculoskeletal examination. Conversely, all horses presented with systemic illness (pneumonia, colitis) should also be evaluated for the presence of laminitis, as this complication is often the limiting factor for the horse's survival. Careful palpation of the lower limbs may indicate increased intensity of digital pulses or changes in the coronary band that may be related to the “sinker” syndrome (distal phalangeal displacement).[4] If laminitis is present as a complicating factor, the clinician should be able to add to the clinical prognosis by using Obel grading (1 to 4).

Evaluation of the circulatory system starts with assessment of heart rate, rhythm, and any presence of murmurs. Mucous membrane color, capillary refill time, scleral injection, palpable changes in the temperature of the ears and extremities, jugular pulsation, and pitting subcutaneous edema are the most common obvious circulatory physical examination parameters. The heart should be auscultated bilaterally, and murmurs graded according to intensity (I to VI or I to V), character, the valvular site, and phase of the cardiac cycle. Arrhythmias usually involve a request for an electrocardiogram (ECG), except with the common findings such as type II heart blocks in clinically asymptomatic horses. Type II heart block in normal horses can usually be obliterated by exciting the horse with a threatening gesture. In addition to electrocardiography, transcutaneous ultrasound examination of the heart and pericardium and transrectal evaluation of the caudal aorta and iliacs for intraabdominal thrombotic lesions can be

used.[5,6] If procedural assessments of blood pressure are needed, a manometer for central venous pressure or a sphygmomanometer with Doppler ultrasound is used on the base of the tail in adults and the tail or inside radius (forearm) in foals.[7]

The respiratory system is similar to the circulatory system in that the breathing rate and mucous membrane color are important assessments. Respiratory effort and the phase of increased work should be assessed (e.g., heaves). Auscultation should be of both the upper (larynx and trachea) and lower airways. Nasal airflow can be determined by wetting the hands and holding them gently over the nostrils so that both intensity and equality of air movement can be assessed. Smelling the breath for fetid or necrotic odors (ozena) is similarly important, and endoscopic evaluation of the upper airways should be an adjunct to abnormal clinical findings. A penlight can be used to visualize the internal nares (septal mucosa). Percussion of the sinuses should be performed for detection of dullness, suggesting sinusitis or the presence of fluid within the sinus cavity. In addition, the head should be carefully examined ventrally and caudally for the presence of lymphadenopathy.

The interpretation of lung sounds has been described elsewhere,[8] and the clinician should make an effort to auscultate dorsal and ventral regions of the thorax bilaterally and document findings as to the location or absence of sounds and the phase of respirations involved.

Percussion is a reliable clinical tool and should be performed in cases of suspected abscess, tumor, or pleural effusion. A pleximeter and tablespoon are the only tools required, although some clinicians are adept at direct finger percussion of the chest. In foals, percussion can be performed by placing a stethoscope on one side of the chest and reaching over the back of the foal to manually percuss the opposite side. Fractured ribs may be recognized in the neonatal foal as palpable asymmetry or a bony crepitus (“clicks”), often with edema of the sternum or elbow coinciding with the fractured side.

Ultrasound has revolutionized the clinical evaluation of the thoracic cavity. Unfortunately, the familiarity of clinicians in thoracic interpretation is directly related to access and frequency of ultrasound use. However, subtle pneumonia, abscess, and pleural effusion represent rapid and definitive objective findings.[5] Because radiographic changes often lag behind clinical disease, serial examinations via ultrasound may be a more accurate way of monitoring response to treatment. Ultrasound may, in fact, eliminate the need for chest radiographs in numerous cases, thereby increasing efficiency and decreasing client costs.

A systematic approach should always be used when examining the horse for gastrointestinal disease. Although the majority of emergencies and referrals are related to colic or acute intestinal disease, the clinician should resist the temptation to focus only on the abdomen, so that important clinical signs relating to other problems are not missed (e.g., gastric ulceration, botulism). If a clinical complaint involving the abdomen is present or in suspected cases of intestinal displacement, obstruction, or volvulus, the gastrointestinal system is initially examined by bilateral auscultation of intestinal sounds. In addition, the abdomen should be auscultated ventrally for sounds similar to “ocean waves” or sand pouring on itself, indicative of the presence of sand within the gastrointestinal tract.[9] In cases in which the gastrointestinal tract is the site of the primary lesion, checking for gastric reflux and performing a rectal examination[10] may become a necessity. Clinicians should strive to become adept at rectal palpation and regard the procedure as a premier diagnostic skill while respecting the risks involved for the patient and veterinarian.

The patient should be observed for the presence of normal prehension, eating, and drinking whenever dysphagia is present or neurologic dysfunction is suspected. The evaluation of the gastrointestinal system should also include a dental examination for the presence of malocclusion and dental abnormalities (e.g., missing or damaged teeth) that can affect prehension or mastication. Accurate notation of affected teeth should be made in the medical record using a universally accepted identification system, such as a numeric system in which the horse's head is divided into four

quadrants, with each tooth described by its own number (e.g., two central upper incisors on horse's right and left would be 101 and 201, respectively). Clinicians should also become adept at dental age determinations, albeit with an awareness of its limitations and subjectivity.[11] Nasogastric intubation is useful in evaluating dysphagia and esophageal blockage (choke) and determining the presence or absence of gastric reflux. In addition, the volume and character (e.g., color, pH, presence of blood or toxic plant material) of reflux obtained can be rapidly evaluated and may aid in the diagnosis.

The use of long endoscopes (e.g., 2 to 3 m) is valuable in the visual assessment of the esophagus and stomach with lesions such as esophageal stricture and gastric ulceration. For a diagnostic endoscopic examination of the stomach, it is recommended that the patient be muzzled or held off feed for at least 10 hours to allow complete visualization of the stomach.[12]

17

18

Ultrasound evaluation of the abdomen in conjunction with aspiration and analysis of fluid visualized may quickly reveal peritonitis, uroperitoneum, hemorrhage, ascites, visceral rupture, or abdominal masses. In adults, palpable abdominal masses and enlarged lymph nodes usually can be scanned transrectally.

The urogenital system can be examined by manual palpation, rectal palpation, vaginoscopic (speculum examination) viewing, endoscopic viewing, and ultrasound. The caudal portion of the left kidney is easily palpated in most horses. Catheterized samples should be obtained (e.g., cultures, urinalysis) before any contaminating invasive procedures (e.g., rectal palpation) are performed and before fluid therapy is initiated. Sphincter tone may be subjectively or objectively (urethral pressure profile) assessed in horses with urinary incontinence or stranguria. Horses with incontinence often demonstrate “scalding” of the perineum and hind legs.

The eyes can be examined by a rapid visual assessment using a penlight. The cornea and cranial and caudal lens capsules can be evaluated by horizontally moving the penlight and noting the crossing light reflexes. Pupillary constriction to light and the “menace” response should be observed, although these reflexes may be significantly slower or absent in the neonate. An ophthalmoscopic retinal examination should be performed whenever the eyes represent the primary complaint, and fluorescein dye strips should be used for the detection of corneal ulcers. Blindfolding of one eye at a time may aid in the assessment of unilateral blindness and should be conducted in a safe area with “blunt” devices contrived as an obstacle course.

The neurologic system examination should involve a consistent procedure for all patients with nervous system disorders (see Nervous System Examination, Chapter 8 and Chapter 35). The patient's attitude, posture, and head carriage should be assessed from afar. The cranial nerves should be evaluated, followed by examination of the spinal reflexes and tail tone. Sensory deficits should be noted at this time. Conscious proprioception and postural responses (e.g., placement, hemihopping, sway) can then be assessed before observing the patient in locomotion. Notes regarding symmetry, asymmetry, ambulation, paresis, muscle atrophy, and upper and lower motor neuron deficits should be documented to aid in determining the sites for any additional ancillary tests such as radiographs or cerebral spinal fluid collection. Blindfolding should be conducted in a safe area, especially for patients with vestibular disease. An area of incline is useful for evaluating the locomotor deficits, especially when the horse is led with the head elevated.

The lymphatic system is usually evaluated merely by recording any obvious lymphadenopathy. This can be regional or local (as in strangles) or generalized (cutaneous lymphosarcoma) and may be appreciated on rectal examination. Lymphangitis or the presence of edema should also be noted.

Once a patient has been admitted to the clinic or hospital, well-organized flow charts should be used for monitoring and assessing the patient.

2.4.2 Use of Ancillary Equipment in the Examination Procedure

Advancing technologies are allowing the practitioner or clinician to add to or replace many physical examination procedures with techniques capable of providing diagnostic information or direct therapeutic intervention. Ultrasound of the chest for the definitive diagnosis of a pleural effusion is an example of an objective procedure that may obviate much of the traditional physical examination procedures used for the clinical diagnosis of pleuropneumonia (e.g., auscultation, percussion, ballottement). For diagnostic equipment to be used in this capacity, it should be available in the physical examination area.

The size of equipment is a determining factor in whether or not a diagnostic tool is suitable for the examination area. For example, equipment such as computerized axial tomography scanners, magnetic resonance imaging (MRI) units, and nuclear scintigraphy units do not currently fit into the space available in most hospital physical plants. Large, modular ultrasound machines can be cumbersome in small areas, although units available for field reproductive use (linear or sector scanners) are appropriate for any area, including vehicle transport. The choice of ultrasound equipment is an individual decision based on need, budget, and available units. Security should also be a consideration in stocking an examination area with equipment and medications. The clinical examination areas of most facilities tend to be high-traffic regions; this may be a primary reason for not stocking certain pieces of equipment in both university practices and private facilities.

2.5 MEDICAL RECORD

In 1968 Lawrence Weed[13] published on the use of the problem-oriented medical record. This system of recordkeeping emphasizes the justifications for daily decision making during hospitalization. Problems are defined by the history, physical examination, and laboratory findings. Daily (and more frequently for intensive care unit patients) *s*ubjective findings (e.g., appetite, attitude) are documented, and *o*bjective data (e.g., heart rate, temperature) are recorded. This information (e.g., patient is febrile) is then *a*ssessed by the clinician, and a *p*lan (e.g., resubmit laboratory tests, change antibiotic medications) is derived based on the assessment. The abbreviated form of this type of medical record is SOAP, and this method is applied to each problem identified. Although the system encourages medical judgment and accountability, it more directly serves as a teaching tool within institutions by which the student's clinical thinking can be evaluated by the in-charge clinician. In private practices the method of record keeping is more flexible and tends to document vital information that primarily serves as an accounting of services and provides a medicolegal record. Unfortunately, many medical records function only as invoices and do not record medical information regarding the patient. This is more often true of ambulatory records but can be found in certain hospital practices. Whichever system is used, the responsibly prepared medical record should provide medical information, justification for charges, and a protection from liability. A thorough medical record further allows for the retrieval of retrospective information. The accumulation of data is beneficial to the communication of clinical caseload experiences to other clinicians for the benefit of their patients.

2.5.1 Medical Record Filing

Two major systems of medical record filing exist: numeric and name filing. Numeric systems offer consistency of the record and avoid the confusion of patients with similar names. The problem of name similarity is primarily confined to the nonregistered breeds of horses. Breed registration requires name approval to avoid duplication, among other undesirable designations. Again, for record-keeping purposes, clinic or ambulatory records for unnamed young horses are best designated by the dam's name and the foal's year of birth (e.g., Curious' 06) and filed by month and year of examination. A “master” admission log should be maintained for record retrieval

purposes, especially when a patient has been seen on multiple occasions. Color coding, along with numbering of the file folders, may be helpful in record retrieval. Computers offer the advantage that records can be retrieved through any one of a number of recall parameters (e.g., problem, client).

2.5.2 Computer-Generated Medical Records

Traditionally, patient medical records (PMRs) are maintained via a manual, paper-based, on-site system of data storage and retrieval as described previously. Before computerization and its acceptance by the medical community, all information regarding patient history, diagnostic testing, and treatment notes was handwritten and filed. Unfortunately, a number of problems coexist with a paper-based system, including illegible handwriting by practitioners or staff, poor integration of patient information (e.g., diagnostic test results and imaging studies filed separately from PMR), and loss of or damage to files.[14] In addition, state veterinary boards require that all patient records and imaging studies be retained by a practice for minimum period of time before they can legally be disposed of. Storage issues can be a particular problem for equine practices that do many prepurchase examinations, in which radiographs may be retained for 10 to 20 years. Although many veterinary facilities currently use computers for various tasks, such as accounting and inventory, few have eliminated the paper-based PMR completely.

Computers offer the advantages of legibility, quick data retrieval, and immense archiving capacity. The need for rapid transfer of medical information from doctor to doctor or doctor to referral facility is being met by advances in computer software and Internet access. Thus, the current trend in human and veterinary medicine is the development and implementation of an electronic medical record (EMR) that is entirely computer generated. An EMR permits one or more individuals, simultaneously, to access laboratory results, imaging studies, and other pertinent patient information.[15] For the equine practitioner, the availability of real-time ultrasound imaging and digital radiography has revolutionized the production and transmission of high-quality diagnostic images, via computer, within moments after they have been taken. This has greatly increased the quality of medicine and efficiency of patient care, allowing general practitioners rapid access to the opinions of specialists at sites distant from the patient. Over time, acceptance of the EMR may result in the complete dissolution of the paper-based medical record.

At this time, several software systems are available to veterinarians that are designed specifically for equine hospitals and include adaptations for ambulatory “off-site” data entry and retrieval.[*][†][‡] In addition to patient information, other applications, such as client invoicing, inventory management, payroll, and so on, are included in these software packages.

Three basic types of systems are currently available to the equine practitioner: standalone and multiuser on-site systems; on-site systems with external synchronization; and Internet-based multiuser systems. The first and second types of systems are similar, but with the addition of external synchronization, patient information can be collected on hand-held devices or laptop computers away from the main hospital (e.g., by ambulatory staff) and downloaded directly to an in-house computer. The third system is the most technologically advanced and offers not only greater efficiency, but the ability to continuously upgrade software. This system offers access to the Internet through either a hospital Web page or a client Internet server and allows practitioners in the field the ability to transmit information, such as digital radiographs, immediately to other doctors, referral hospitals, or specialists throughout the world. These connections can be made via wireless (e.g., cell phone) or direct Internet access (e.g., phone line, cable). Currently, certain veterinary laboratories are capable of sending test results directly to the PMR as soon as they are available.[‡][§] Another advantage to this system is that all information

contained in the EMR can be stored on an off-site server and downloaded to the hard drives of in-house computers.

This technology can be a cost-effective, important tool in modern practice management that increases efficiency and quality of patient care and dramatically reduces storage requirements.

2.5.3 Record Keeping for Special Purposes

The Drug Enforcement Administration (DEA) requires veterinary practices to maintain detailed inventory records for scheduled drugs. Drug inventory and use must be documented in a record book kept accessible to the area contained behind two locks where the scheduled drugs are stored. Records must be documented to either a clinic area where a minimal volume of drug can be kept (e.g., a single vial of diazepam), or for patient use. Use should identify the patient, volume used, date, and authorized person who obtained the drug. The drug use should be further documented in the PMR so as to account for the volume having been depleted from the inventory. A monthly or bimonthly accounting suitable for inspection should be conducted from the storage inventory and patient files to accurately account for scheduled drug use. This same accounting and inventory system applies to ambulatory vehicles.

Occupational Safety and Health Administration (OSHA) records are comparable to the DEA ongoing inventory and use records and are stringent in terms of compliance with OSHA regulations.[16] Documentation regarding safety procedures (e.g., fire safety inspections) is required after an initial inspection for labeling and safety protocol. Upgrading of Material Safety Data Sheets (MSDSs) is a further requirement and should comply with current standard.

3 Chapter 3 Pain

Consulting Editors

James N. Moore

3.1 ANATOMIC AND PHYSIOLOGIC BASIS OF PAIN

3.1.1 What Is Pain?

Steven G. Kamerling

James N. Moore

The International Association for the Study of Pain describes pain as an unpleasant sensory and emotional experience associated with actual or imminent tissue damage.[1] However, this definition continues to be debated. Although most agree that pain is “perceived” by organisms that have a nervous system, the degree of “suffering” experienced by various animals is controversial. In human medicine many believe that pain must be defined in the context of intelligence, consciousness, and the memory of painful experiences. However, pain reactions are readily recognizable in large animals and are clearly “remembered” by animals that have experienced them. Perhaps what differentiates humans and other animals is the complexity and manner in which pain is expressed. In verbally competent humans, linguistically reported pain is the gold standard. In human neonates and animals, recognition of pain reactions or behaviors becomes of paramount importance. Despite phylogenetic differences among members of the animal kingdom, it is incumbent on the veterinary practitioner to presume that large animals perceive, react to, and suffer from painful stimuli and experiences.

3.1.2 Nociceptors and Nociception

The International Association for the Study of Pain's definition of pain highlights two important aspects of pain, namely a sensory discriminative component and an emotional, or affective, component. The sensory component of pain is often referred to as *nociception,* or the sensory reception of noxious or injurious stimuli by nociceptors. Nociceptors are sensory neurons having free, unmyelinated nerve endings. These nociceptors respond selectively to noxious stimuli but cannot be characterized based purely on histology. The three main functional types of nociceptors are mechanical, thermal, and chemical. Anatomically they are classified as A-delta or C-polymodal. A-delta nociceptors are unimodal, high-threshold, small-diameter, myelinated fibers that respond to deforming mechanical stimuli such as tissue compression. They typically do not respond to excessive temperatures or chemicals unless sensitized. C-polymodal nociceptors are small-diameter, unmyelinated, slowly conducting fibers that respond to chemical, thermal, and mechanical extremes. Thermal nociceptors, typically present in skin, respond to temperatures exceeding 45° C. For example, radiant heat sufficient to raise the temperature of the skin over the withers (44° to 50° C) elicits the protective twitch reflex within 5 seconds. Chemical nociceptors respond to noxious chemicals (e.g., caustics, acids, bases, hypertonic solutions) or inflammatory mediators (e.g., prostaglandins, bradykinin). Nociceptors exist in muscles, the skin, the periosteum, most internal organs, the tooth pulp, the cornea, and the meninges. With the exception of pain in the meninges (i.e., headache), “pain” in these tissues can be readily recognized.

Nociceptors serve to warn an animal of imminent or ongoing tissue injury. This warning typically elicits protective reflexes, such as the skin twitch reflex described previously, that attempt to separate the animal from the noxious stimulus. The limb withdrawal reflex after the application of a hoof tester can be used as a measure of pain threshold in horses.[2] Pain threshold can be defined as the stimulus intensity (e.g., temperature, pressure) that is sufficient to elicit a behavioral pain response. Nonsteroidal antiinflammatory analgesics increase the amount of hoof compression tolerated by laminitic horses,[3] and opioid analgesics lengthen the time required to produce the limb withdrawal and skin twitch reflexes in horses exposed to noxious heat.[4] Because these analgesics act preferentially on nociceptors and their peripheral and central pathways, these reflexes represent true "pain responses" by the horse. Clearly, such reflexes are critical in protecting horses from hostile environmental insults.

3.1.3 Inflammatory Pain and Hyperalgesia

The reflexes discussed previously signal imminent tissue injury; but what happens when tissues actually are damaged? The sensitivity of damaged tissues (especially the skin) to pain and other stimuli differs from that of normal intact tissue. The first phenomenon observed in injured tissues is allodynia, the production of pain by a stimulus that previously was nonpainful. For example, lightly probing the withers of a horse does not usually elicit a response. However, gently stroking the same site in horses with severe dermatophylosis can elicit a vigorous, attention-getting twitch response. This is an example of allodynia. The second phenomenon is hyperalgesia, which occurs when previously painful stimuli produce pain of greater magnitude, duration, or area. Osteoarthritis is a condition associated with inflammatory hyperalgesia, in which weight bearing on already painful joints results in a greater degree of pain. Nonsteroidal antiinflammatory drugs are particularly effective in reducing hyperalgesia but have little effect on pain sensitivity in healthy tissues.

The phenomenon of hyperalgesia is a subject of considerable research. Current theories suggest that persistent tissue injury is mediated by numerous endogenous chemicals, which alter both the peripheral and the central nervous systems. Peripheral hyperalgesia occurs at the site of injury and is mediated by the release and conversion of arachidonic acid into prostaglandins (mainly PGE_2) and leukotrienes (mainly LTB_4 products). Together with bradykinin and histamine, these mediators render nociceptors hyperresponsive to noxious stimuli. Serotonin from platelets and mast cells, interleukins 1 and 8, and tumor necrosis factor from immune cells contribute to hyperalgesia. Retrograde release of substance P and calcitonin gene-related peptide from neighboring nociceptors amplifies the hyperalgesia. The sympathetic nervous system appears to be involved in hyperalgesia, as norepinephrine, released from sympathetic efferents, provides additional amplification. In fact, sympathectomies have been used to minimize certain types of intractable pain.

More recently adenosine (and other products of adenosine triphosphate [ATP] metabolism) and the excitatory amino acid glutamate have been implicated in the pain amplification cascade. The short-lived gaseous neurotransmitter nitric oxide is produced at inflammatory sites and by pain neurons in the central nervous system. Nitric oxide is formed by the action of nitric oxide synthase, an enzyme, on L-arginine. In fact, nitric oxide synthase inhibitors (e.g., L-NAME) reduce inflammatory pain in several laboratory animal species. Nerve growth factor has also been recognized as contributing to hyperalgesia. A number of these mediators appear to exist in horses and other species. Currently they are targets for pharmacologic intervention in the pain process.[5]

Hyperalgesia also appears to occur centrally within the spinal cord, mirroring the peripheral event. Many of the same transmitter substances released peripherally by nociceptors are released in the spinal cord. Persistent tissue damage triggers the release of substance P, and glutamate/aspartate from the intraspinal terminals of the nociceptors, activating NK-1 and NMDA/AMPA receptors, respectively. These powerful excitatory transmitters

appear to lower the response thresholds of second-order dorsal horn neurons. This process appears to mediate both allodynia and hyperalgesia and is often referred to as *secondary* or *central hyperalgesia*. Recent evidence suggests that prostaglandins are also released into the spinal cord from peripherally activated nociceptors. Therefore nonsteroidal antiinflammatory drugs that inhibit prostaglandin synthesis may act at the site of injury and centrally to relieve inflammatory pain. Lastly, persistent tissue inflammation may recruit previously inactive neurons or silent nociceptors, which are quiescent in normal tissue. These nociceptors may further enhance the excitability of the spinal cord to peripheral pain.

The prevention of secondary hyperalgesia is of great interest in human and veterinary medicine. It has been proposed that if the barrage of sensory impulses from damaged tissue can be prevented from influencing the spinal cord, less central hyperalgesia should occur. This has been supported by the results of several studies. For example, intra-spinal administration of local anesthetics and opiates to animals before surgery results in less postoperative pain than if the same drugs are administered postoperatively. Thus, the preemptive use of analgesics and anesthetics may reduce postoperative pain and improve recovery from surgery. The relatively common procedure of lumbar puncture should lend itself well to preemptive analgesic therapy in horses and other large animals. From these approaches, it has been suggested that the developing nervous system remembers pain. Stated another way, pain changes the nervous system. Consequently, the long-term impact of surgery-induced pain should perhaps be reexamined.

3.1.4 Pain Transmission Within the Central Nervous System

The simplest pain responses are unconscious motor reflexes. These reflexes are segmentally controlled within the spinal cord and do not require conscious intervention. Animals whose spinal cords have been severed can still demonstrate withdrawal reflexes below the level of transection. Such reflexes normally serve to protect animals from injury.

Noxious stimuli are initially transduced by A-delta and C nociceptors, which then synapse with spinal cord dorsal horn neurons in several of the layers or laminae. Lamina I (i.e., the marginal zone), the most superficially located layer, receives A-delta and C fibers that carry pain and temperature information. Lamina II (i.e., the substantia gelatinosa) consists mostly of interneurons that integrate information from A-delta and C fibers from Lissauer's tract. Warmth, cold, and pain are integrated and modulated in laminae III and IV. Lamina V and VI neurons are critical in pain processing and modulation. They receive information primarily from thermosensitive and mechanosensitive nociceptors and may project directly to the thalamus and brain. These neurons also receive input from descending brainstem pathways capable of modulating pain signals.[6] The relatively superficial location of the pain pathways in the spinal cord helps explain the rapid and selective analgesia achieved after intrathecal administration of local anesthetics in horses.

24

25

The dorsal column pathway and spinothalamic tract are involved in conveying pain signals from the spinal cord to the brainstem or brain. There are species differences in the roles of each of these pathways. For example, the spinothalamic tract is more important in pain transmission in primates than in nonprimates. The dorsal column-medial lemniscus pathway carries information about pain, touch, and pressure. It is unique in that some nociceptors travel directly to the brainstem via this pathway, resulting in rapid contact between periphery and brain. The brainstem plays a key role in the autonomic responses to pain (see later). Cells from the medial lemniscus synapse with the intralaminar nuclei of the thalamus. The spinothalamic tract carries information about pain, temperature, and to some extent touch. However, spinothalamic tract cells originate mainly in lamina V and do not synapse with the brainstem. Instead they innervate the ventral posterior and other nuclei of the thalamus. The trigeminal nerve contains nociceptors that convey temperature and pain information from the face, jaw, teeth, tongue, and lips. These trigeminal nociceptors synapse with the nucleus of the spinal tract (similar to the

spinothalamic tract) and go on to form the trigeminothalamic tract. This is a particularly important pathway in horses, considering that orofacial pain, applied through a bit, is used to command attention and control motor behavior. The spinothalamic tract pathways appear to play an important, albeit not exclusive, role in chronic burning pain states especially involving the polymodal nociceptors. Overall, it is generally believed that the lateral thalamus is involved in the discriminative sensory component of pain, whereas the medial thalamus mediates the emotional and motivational aspects of pain.[7]

Processing of pain in cortical sites may to some extent underlie species differences in the experience and expression of pain. Clearly the relative size and complexity of the cerebral cortex differs among animals. Modern functional imaging studies show that painful stimuli activate subcortical regions such as the periaqueductal gray, the hypothalamus, the amygdala, and the cerebellum. However, painful stimuli selectively activate cortical sites such as the insular and cingulate cortices, which receive input from the thalamus. It is interesting to note that the frontal and cingulate cortices of the cerebrum seem to be necessary for experiencing suffering. Early human studies have indicated that patients receiving frontal lobotomies were able to describe a painful stimulus but not to be concerned about it.[7,8]

3.1.5 Types of Physical Pain

Pain has often been categorized as superficial, deep somatic, and visceral. Cutaneous or superficial pain tends to be definitive, well localized, and constant and may follow the distribution of somatic nerves. Deep somatic and visceral pain tends to be diffuse, dull, poorly localized, and periodic and elicits more pronounced autonomic changes. Visceral pain may also be referred to other deep or cutaneous sites.

It may be more relevant for the practitioner to identify pain in terms of its site of origin. Visceral, musculoskeletal, and cutaneous areas are perhaps the most recognizable sites for pain in large animals. Rapid distention, ischemia, pulling on the root of the mesentery, or high luminal pressure in any portion of the hollow viscus elicits pain behavior in horses and cattle. This is most rapidly characterized by biting, looking at, or kicking at the abdomen or thorax and probably reflects an attempt to remove the painful stimulus from the referred site. Dorsolateral rolling, whole body hyperextension, and groaning can be observed in horses with severe intestinal colic. Muscle pain can be induced by strenuous exercise, trauma, or sustained contraction. Alterations in weight bearing, abnormal body postures, and lameness and tenderness on palpation are the most recognizable signs. Severe rhabdomyolysis (“tying up”) certainly initiates dramatic changes in muscle tension. Joint pain accompanies acute traumatic, infectious, and degenerative arthritis and is associated with decreased range of motion, hypoactivity, and lameness. Cutaneous pain usually results from traumatic skin injury, bite wounds, or infections. Typically these sites of injury may be guarded, scratched, or licked. Exaggerated withdrawal or evasive reflexes may occur in an attempt to remove the noxious stimulus. Corneal pain can be elicited by chemical, thermal, or mechanical stimuli and is often accompanied by increased tear production and blinking. Dental pain, perhaps the only sensation in teeth, is difficult to detect in large animals but has been associated with head tossing, jaw opening, or mandibular activation. Whereas headache pain is of considerable concern in human medicine, there have been no systematic attempts to identify or characterize this phenomenon in large animals.

3.1.6 Autonomic and Emotional (Affective) Components of Pain

Affective, or emotional, responses to painful stimuli appear to vary widely in the animal kingdom and within a species. The neuroanatomic correlates of emotional pain involve higher brain functions and add another dimension to simple reflex responses. Humans experiencing pain often use terms such as *exhausting, terrifying, sickening, cruel,* and *vicious*. Changes in facial expression, body posture, and gestures signaling disgust, fear, and

anger have also been described.[9] These expressions serve to alert others to an individual's condition of pain. Some of these human “emotions” may have large-animal counterparts. In addition to site-related motor responses, changes in temperament have been described.[10] Animals showing aggression in the form of kicking, biting, striking, head butting, teeth grinding, fighting, and escaping may be in pain. Grunting, moaning, or squealing may be heard. On the other hand, some individuals may appear docile and defeated. Changes in facial expression such as dull eyes; drooping eyelids, ears, and head; excessive tears; and hyperresponsiveness to light or sound may be observed. Thus, animals and humans may share the fear-, anxiety-, and anger-associated expressions of pain.

Along with the expression of pain behaviors, autonomic disturbances in homeostasis occur. It is worth noting that some nociceptive dorsal horn neurons synapse with the pontine and midbrain reticular formation, the lateral periaqueductal gray, the ventral medulla, and the hypothalamus. Nociceptive activation of the ventral medulla results in increases in heart rate, respiratory rate, and blood pressure. Activation of the hypothalamus results in the release of vasopressin and adrenocorticotropic hormone (ACTH), which affect hemodynamics and blood glucose concentration. Stimulation of the reticular formation results in enhanced vigilance and attention. Activation of the periaqueductal gray results in recruitment of an endogenous, descending pain suppression system (see endogenous pain suppression later), which “attempts” to modulate the intensity of painful stimuli at the level of the spinal cord. These gross autonomic and metabolic responses contribute to the aversive and arousal nature of the painful experience.

25

26

In addition to its aversive quality, pain can motivate and be learned and avoided by animals. The application of acute pain is used universally to control equine behavior. Common examples include the use of a bit to coerce movement, the application of a whip to increase racing performance, the application of a twitch for restraint, and sole “soring” to increase gait animation. There is little doubt that the average horse learns and remembers the aversiveness of these stimuli and “works” to avoid them. However, acute pain (e.g., kicking, biting) is inflicted conspecifically to establish social and reproductive dominance within a herd. Pain can also be used to subdue adversarial predators. Past experiences can profoundly influence the affective response to pain. Factors such as anticipation, anxiety, and fear can negatively influence future pain response. Horses that appear “head shy” after years of abuse have learned, all too well, how to detect and avoid imminent tissue injury.

3.2 PATHOPHYSIOLOGIC EFFECTS OF PAIN

3.2.1 Acute Pain

Pain of short duration alerts animals to potential injury and is adaptive for survival. It is also a signal to stop using injured tissues, to promote healing. Acute pain usually elicits quick behavioral action and resolves without a significant disruption in homeostasis. Acute pain may be caused by environmental stimuli, trauma, surgery, acute medical conditions, or normal physiologic processes (e.g., parturition). A common constellation of signs may be seen in large animals. Neurologic signs include behavioral excitement, confusion, tremors, rigidity, twitching, hyperreflexia, and ataxia or immobility, paralysis, and inertia. Cardiorespiratory signs include hypertension, tachycardia, vasospasm, venous stasis, and tachypnea. Gastrointestinal hypomotility or hypermotility, urinary retention, sweating, and hyperthermia may also occur. Acute pain of a more debilitating nature may produce more profound changes in posture, temperament, and locomotion. Head and neck ptosis, rolling on the ground, hyperextension or hyperflexion of the body and neck, widened stance, and prolonged sternal or lateral recumbency may be observed. A spectrum of emotional reactions from aggressiveness, anxiety, self-mutilation, and vocalization (moaning, grunting) to marked depression may occur. Specific lamenesses and weight-bearing deficits may accompany more specific musculoskeletal insults.[10]

3.2.2 Chronic Pain

Fortunately, most acute pain resolves and homeostasis is restored. However, extensive tissue injury or disease may result in pain that persists for days or weeks. Such pain is often associated with inflammation and accompanying allodynia and hyperalgesia. Pain states that persist for months, even after healing has occurred, are classified as chronic. Chronic pain often includes a continuation of the acute manifestations described previously. However, more global, systemic changes emerge as unabated pain continues.

Chronic pain can be best assessed by noting changes in eating, sleeping, social behavior, reproductive activity, personality, growth and performance, body position, and activity level and certain physiologic signs. Chronic unrelieved pain may result in depression, inappetence, weight loss, and reduced growth or milk production (e.g., in cows or goats). Musculoskeletal pain may actually impair mobility and prevent normal social competition for food, contributing to further weight loss. Disruption in sleep-wake cycles may add to the overall debility. Psychologic alterations expressed as personality changes toward an owner or cohort may emerge, along with a positional change in the herd hierarchy. Conspecific grooming and other social interactions may decline as well. Signs of psychomotor stress may develop including trembling and rigidity, as well as stereotypies such as pacing, head shaking, pawing, scratching, and stall walking.

The persistent disruption in homeostasis may have serious long-term consequences. Increased release of cortisol, catecholamines, and renin is associated with pain and other forms of distress. These hormonal responses can impair normal cardiovascular function and may contribute to hypertension. In fact, acute changes in plasma concentrations of cortisol, catecholamines, glucagon, blood glucose, insulin, β-endorphin, lactate, and growth hormone have been used as indirect measures of pain. Depending on the site of pain or injury, prolonged recumbency in large animals can result in pulmonary congestion, hypoxemia, pneumonia, and altered thermoregulation. Data also suggest that chronic pain may be immunosuppressive.

Although the use of analgesics for pain relief is not discussed in this chapter, it is worth noting that analgesics can be used to diagnose pain. Opiates elevate the nociceptive threshold by preferentially inhibiting dorsal horn neurons in pain reflex pathways. This in part explains their ability to dull pain sensations. This occurs without altering other sensory modalities (e.g., touch, pressure). Opiates also activate (1) descending brainstem inhibitory pathways, which alter spinal pain transmission, and (2) ascending pathways to the nucleus accumbens, amygdala, frontal cortex, striatum, thalamus, hypothalamus, and ventral hippocampus.[11] These latter sites are intimately associated with emotionality and the affective and autonomic responses to pain. Therefore, relief of the aforementioned behavioral signs and symptoms by opioids is indirect evidence that pain contributed to their expression.

3.2.3 Are Animal and Human Pain Equivalent?

Whether nonhuman animals feel pain the way humans do continues to be debated, along with the need for analgesics. Arguments favoring a difference include the following:

- The relative speed with which animals recover from major surgery
- Stoicism in the face of severe injury
- Anatomic differences in pain pathways

- Lesser-developed cortices in nonhuman animals
- Unusual responses to some analgesic drugs

Arguments favoring a similarity include the following:

- The hypothesis that stoicism is adaptive and reflects a difference in pain expression rather than perception.
- Acute and chronic pain symptoms and sequelae are similar.
- Autonomic and endocrine responses to pain are similar.
- The same chemical, thermal, and mechanical stimuli elicit pain in humans and animals.
- The same pain-mediating neurotransmitters and modulators are present in humans and animals.
- There are qualitative similarities in the neuroanatomic pain pathways.
- Surgical procedures (e.g., auricular, thoracotomy) and diseases (e.g., arthritis, pancreatitis, colic) that are painful to humans are also painful to animals.
- Opioids are universally analgesic.

Although these arguments persist, many large animal practitioners avoid using analgesics because they mask symptoms and impair the diagnosis of underlying disease. Drugs such as nonsteroidal antiinflammatory drugs may also produce serious side effects such as gastric and abomasal ulcers. On the other hand, public and regulatory agencies insist that animal pain be recognized, avoided, and treated whenever possible.

26 27

3.2.4 Endogenous Pain Suppression

The expression of pain seems to differ widely across and within animal species. Some animals (and humans) cry out at the slightest provocation, whereas others seem to endure traumatic insults interminably. Most veterinary practitioners have had the misfortune of observing a horse finish or perhaps win a race, undeterred, with a fractured cannon bone. One may ask how this occurs. There is growing neurochemical and neuroanatomic evidence for the existence of an endogenous pain suppression system with segmental and suprasegmental components.

The segmental component is thought to exist within the dorsal horn of the spinal cord. It is probably this system that we activate when we lightly but vigorously rub a recently acquired bruise for pain relief. The licking or light rubbing of a fresh wound by an animal would represent the corollary process. The light touch or vibration stimulates larger-diameter, A-beta mechanoceptive afferents at or near the site of injury. At the same time, A-delta and C fibers are transmitting nociceptive signals from the injured site. These fibers somatotopically converge on a common spinothalamic tract cell. However, the A-beta fiber is thought to activate an inhibitory interneuron en route to the spinothalamic tract cell. Thus, the large fiber damps down or closes the gate to pain signals delivered by the neighboring nociceptor. This formed the basis of the Gate Control Theory of Pain by Melzack and Wall.[12] This theory has also been advocated to explain the operation of transcutaneous electrical nerve stimulation devices. These devices deliver nonnoxious electrical stimuli to the skin via electrodes placed at or near injured or inflamed sites. The direct current (DC) electrical current activates mainly large-diameter, cutaneous, low-threshold mechanoceptors, which damp down nociceptor input from converging dermatomes.

Variations in impulse magnitude, shape, frequency, and duration are selected to maximize this effect. Transcutaneous electrical nerve stimulation devices are used routinely in human medicine and by racetrack practitioners to reduce inflammatory pain.

For function in the face of severe pain and distress, certain endogenous coping mechanisms exist that modulate the intensity and quality of pain. The best understood of these is the descending pain suppression system. This system consists of a family of descending neurons from the hypothalamus, midbrain periaqueductal gray, rostral ventromedial medulla, and dorsolateral pontine tegmentum. These pathways form a cascading neuronal circuit that ultimately influences activity in pain-sensitive spinothalamic tract cells in the spinal cord dorsal horn. The neuronal components of this descending system are activated by pain and other stressful stimuli.[11]

The command center of the system is the periaqueductal gray. The periaqueductal gray contains both opiate receptors and enkephalins. Enkephalins are small, short-acting peptides that bind to opiate receptors and mimic the actions of morphine. In fact, the name is derived from the term *en*dogenous *cephalic* peptide. Activation of or application of morphine or enkephalin into the periaqueductal gray activates the rostral ventromedial medulla. The rostral ventromedial medulla then releases serotonin from its terminals in the spinal cord dorsal horn. Serotonin is an indoleamine neurotransmitter involved in the control of mood, vigilance, sleep, and pain threshold. Once released into the spinal cord, serotonin activates specific dorsal horn interneurons that contain enkephalin. The enkephalins then act on opioid receptors located on pain-responsive neurons in the spinal cord. Stimulation of these opioid receptors inhibits the pain-responsive cells, rendering them less excitable by nociceptive signals from the periphery. The periaqueductal gray also activates the dorsolateral pontine tegmentum, which sends its norepinephrine-releasing neurons to the dorsal horn as well. The norepinephrine acts on α_2-receptors also located on pain-sensitive neurons, inhibiting them. Thus, three separate neurotransmitter systems play a role in endogenous pain modulation-serotonin, enkephalin, and norepinephrine. Activation of these systems ultimately results in inhibition of pain reflexes and pain sensations (i.e., analgesia).[11] This mechanism not only explains how pain can induce endogenous analgesia, but also how intrathecal and systemically administered morphine and xylazine relieve pain.

Another important morphine-like peptide involved in the production of endogenous analgesia is β-endorphin. Pain, parturition, exercise-stress, acupuncture, and surgery increase circulating levels of this pituitary hormone along with ACTH. β-Endorphin, which can be detected in plasma and cerebrospinal fluid, is larger and longer-acting than enkephalin and also binds to opioid receptors. It produces analgesia when administered, and its effects can be blocked by the opioid antagonist naloxone. Endorphins are involved in regulating pain threshold in horses, as they follow the same diurnal rhythm.[13] Plasma concentrations of endorphins and pain threshold also appear to increase after strenuous exercise in thoroughbred horses.[14] Endogenous opioids are also present in the gastrointestinal tract and are thought to modulate muscle tone and possibly sensation. We believe that this system is operative in the horse, as we have observed colic pain and diarrhea in horses receiving the opioid antagonist naloxone.[15]

3.2.5 Approach to Diagnosis of Abdominal Pain

Diseases characterized by abdominal pain occur commonly in horses and ruminants. In most instances the painful stimuli originate secondary to an intestinal obstruction or malposition (Boxes 3-1 and 3-2). In male or castrated male sheep and goats, the most common cause of abdominal pain is urolithiasis. When the pain is intestinal in origin, there may be distention of the intestinal wall with gas or ingesta, increased tension on the mesentery, or ischemia of the intestine. The clinical signs exhibited by the animal depend on the species, the age of the particular animal, and the severity of the underlying cause. The presence of abdominal pain may be characterized

by outward clinical signs ranging from mild depression to repeated pawing or stamping of the feet to violent behavior. For example, in the horse many problems can cause abdominal pain, ranging from distention of the cecum with gas to simple obstruction of the intestinal lumen with ingesta to strangulation obstruction of the intestine (see Colic, Chapter 7). Consequently the clinical signs exhibited by the horse may range from repeated pawing with a front foot and turning around to look at the abdominal region to uncontrollable rolling and thrashing. Although the severity of the clinical signs exhibited by the horse tends to correlate with the severity of the underlying problem, exceptions to this rule occur commonly. Thus, the importance of performing a thorough physical examination in these instances cannot be overstated. Finally, the age of the animal must be considered in light of the clinical signs manifested. For example, the foal frequently swishes its tail from side to side and rolls up onto its back as part of its characteristic response to the presence of abdominal pain. In addition, bruxism is not an uncommon manifestation of pain in foals. Abdominal pain caused by liver disease is uncommon; however, it can occur in cases of severe hepatic lipidosis (especially in ponies and miniature horses). In horses with cholelithiasis, intermittent abdominal pain is the most common clinical sign, presumably resulting from bile duct distention.[16]

27

28

3.2.5.1

Box 3-1 Causes of Abdominal Pain in the Horse

3.2.5.1.1

Common Causes

- Accumulation of gas
- Intestinal obstruction
- Intestinal muscle spasm (cramps)
- Gastric ulcers (foal)
- Meconium impaction (neonate)
- Parturition

3.2.5.1.2

Less Common Causes

- Colitis or enteritis
- Colonic displacements
- Colonic volvulus
- Ileal impaction

Ileus

Intestinal foreign body (sand, enterolith, phytobezoar)

Irritant cathartics

Parasympathomimetic drugs

Peritonitis

Proximal enteritis (duodenitis-jejunitis)

Small intestinal strangulation obstructions

Thromboembolism

Uroperitoneum (ruptured bladder in newborn)

Uterine torsion

3.2.5.1.3

Uncommon Causes

Acute hepatitis

Acute toxic enteritis

Ascarid impaction

Botulism

Cantharidin toxicity

Cholelithiasis

Rhodococcus (Corynebacterium) equi mesenteric abscess

Equine viral arteritis

Gastric dilation (cribbing, wind sucking)

Hernias (diaphragmatic, umbilical, other)

Intraabdominal adhesions

Intussusception

Malignant mesothelioma

Mesenteric abscess *(Streptococcus equi, Streptococcus zooepidemicus)*

Necrotizing enterocolitis (foals)

Neoplasia

Pedunculated lipoma

Plant poisonings

Potomac horse fever

Psychogenic colic

Rectal tear

Stenosis or stricture of bowel

Tetanus

Urolithiasis

3.2.6

Approach to Diagnosis of Chest Pain

Generally pain associated with conditions involving the pleural cavity is severe. The painful stimuli usually originate from the inflamed parietal pleura because few nociceptors are present in the visceral pleura. Because of the primary involvement of the parietal pleura, the pain is referred to a site directly overlying the thoracic wall. Consequently, if the focus of inflammation is relatively well localized, as occurs with traumatic

reticuloperitonitis-pericarditis, sensitivity to externally applied pressure may be restricted to one area of the chest wall (Box 3-3). If, however, the inflammation is generalized, as in equine pleuropneumonia, pain may be elicited by applying digital pressure over several sites. Similarly, because movement of the inflamed tissue accentuates the production of painful impulses, the animal remains stationary and is reluctant to lie down; the elbows are abducted; the chest wall is splinted; and the respiratory excursions are shallow, rapid, and accompanied by grunting. It is common that the severity of pain is reduced as the volume of pleural effusion increases.

3.2.6.1

Box 3-2 Causes of Abdominal Pain in Ruminants

3.2.6.1.1

Common Causes

- Abomasal gas (calf)
- Abomasal volvulus
- Abomasal ulcer
- Accumulation of gas (bloat)
- Cecal displacement or torsion
- Intestinal torsion or volvulus
- Intussusception
- Peritonitis
- Traumatic reticuloperitonitis
- Urolithiasis
- Uterine tear with peritonitis or adhesions
- Vagus indigestion

3.2.6.1.2

Less Common Causes

- Abomasal displacement

Abomasal impaction

Atresia coli (neonate)

Cholelithiasis

Cystitis or pyelonephritis

Enterotoxemia

Enterotoxigenic colibacillosis (neonate)

Fat necrosis with intestinal obstruction

Ileus

Intestinal adhesions

Rumenitis

Thrombophlebitis

Uterine torsion

3.2.6.1.3 Uncommon Causes

Hepatitis or liver abscess

Intestinal neoplasia

Plant poisonings

3.2.6.2 Box 3-3 Causes of Chest Pain in the Horse

3.2.6.2.1 Common Causes

Lung abscess

Pleuritis

Pleuropneumonia

Pneumonia

3.2.6.2.2 Less Common Causes

Choke

Fractured ribs

Mediastinal masses (abscess, tumor)

Neoplasia

Osteomyelitis

Ruptured esophagus

White muscle disease (rhabdomyolysis, tying up)

3.2.6.3 Box 3-4 Causes of Chest Pain in Ruminants

3.2.6.3.1 Common Causes

Pleuropneumonia

Pneumonia

Shipping fever complex

Thrombosis of the caudal vena cava

Traumatic reticuloperitonitis-pericarditis

3.2.6.3.2

Less Common Causes

Acute bovine emphysema (atypical interstitial pneumonia)

Choke

Fractured ribs

Mediastinal masses (abscess, tumor)

Osteomyelitis

Pleuritis

Ruptured esophagus

Chest pain may also develop acutely as a result of pulmonary arterial thromboembolism in cattle (Box 3-4). Presumably the acute development of pulmonic ischemia in such instances causes the local generation and release of several proinflammatory substances. Most of these problems occur secondary to thrombosis of the caudal vena cava.

Although less dramatic than that accompanying either pleuropneumonia or thromboembolism, pain also accompanies pneumonia and pulmonary contusions. The pain associated with pneumonia occurs secondary to pleural irritation and is well localized only if the parietal pleura is involved. Because the pain appears to be most evident during forced respiratory excursions, splinting of the thorax is common. Chest pain may also occur secondary to traumatic incidents. Although rib fractures occur rarely in horses and ruminants, they must be given some consideration in an animal exhibiting clinical signs of chest pain. Rib fractures occur more commonly in neonatal foals during birth and may result in respiratory distress. Obviously the force required to fracture a rib will cause severe bruising and inflammation of the underlying pleura.

3.2.7

Approach to Diagnosis of Pain in the Extremities

Although the reflex contraction of flexor muscles occurs with all types of pain, this reflex is most evident with pain in the extremities. Thus, as a result of a painful stimulus and to minimize the continued stimulation of the nociceptors in the affected area, the animal alters its stance or gait to protect the source of pain. Therefore, it is vital that the animal be inspected initially from a distance to determine which limb is involved. It may be necessary to move the animal at either a walk or a faster gait to identify the affected limb. It is important for the clinician to recognize that (1) the painful impulses may originate from several tissues in the extremity, including the skin, joint, periosteum, muscle, and the sensitive laminae of the distal phalanx; and (2) several factors may be contributing to the source of the pain. These factors may represent a particular conformational, breed, or familial predisposition toward development of the condition, the effects of nutritional imbalances on the development or stability of either bone or soft tissue, the effects of the use or performance of the animal, the possible involvement of infectious agents, and the effects of trauma (Boxes 3-5 and 3-6).

Careful palpation of both the soft tissues and the bones of the limbs must be performed to identify sources of inflammation or pain. Furthermore, the responses, if any, to flexion and extension of the joints must be evaluated, and the examination performed in a systematic manner. It may be necessary to inject a local anesthetic over a sensory nerve or into a synovial structure (joint, tendon sheath, bursa) to prevent the conduction of pain impulses to the central nervous system. The judicious use of local anesthesia combined with a careful physical examination should allow the affected site to be identified. On the basis of this information, the clinician can then make efficient use of other diagnostic aids (radiography, synovial fluid analysis, scintigraphy, ultrasonography) to determine the underlying cause of the pain and direct therapy accordingly.

3.2.8

Approach to Diagnosis of Back and Neck Pain

The association between pain arising from either the back or the neck and irritation of spinal nerve roots has not been as well established in large animal species as it has in small animals and people. However, there is considerable evidence that muscle damage, ligamentous strain, sacroiliac strain, and either fracture or overriding of the dorsal spinous processes of the thoracic vertebrae cause varying degrees of back pain in horses.[17,18] Attention must be given to the detection and treatment of exertional rhabdomyolysis in horses and postanesthetic myopathy in horses and cattle (Boxes 3-7 and 3-8). Each of these conditions is characterized by painful impulses originating from ischemic or damaged muscles. Similarly, the development of nutritional myopathy associated with selenium deficiency must be considered in horses and ruminants in certain areas of the country. All large animals are susceptible to traumatic incidents that may result in fracture of either cervical or sacral vertebrae. Horses occasionally rear up and fall over backward, fracturing the sacrum or dorsal processes of the thoracic vertebrae. Cattle fracture the pelvis or develop sacroiliac luxations when they slip on concrete floors, often when mounting is occurring during estrus.

29

30

3.2.8.1

Box 3-5 Causes of Pain in Extremities of the Horse

3.2.8.1.1

Common Causes

Degenerative joint disease

Hoof wall defects

Improper trimming or shoeing

Lacerations

Ligamentous strain (sprain)

Navicular disease

Sole abscesses and bruises

Synovitis

3.2.8.1.2

Less Common Causes

Bucked shins

Cellulitis or abscess

Epiphysitis

Flexural deformities (contracted tendons)

Fractures

Desmitis

Laminitis

Osteomyelitis

Osteochondrosis

Septic arthritis or physitis

Tenosynovitis

3.2.8.1.3

Uncommon Causes

Keratoma

Neoplasia

Purpura hemorrhagica

Toxins

Ulcerative lymphangitis

Upward fixation of the patella

White muscle disease (rhabdomyolysis, tying up)

3.2.8.2

Box 3-6 Causes of Pain in Extremities of Ruminants

3.2.8.2.1

Common Causes

Degenerative arthritis

Foot rot

Interdigital fibroma

Lacerations and foreign bodies

Laminitis (horizontal fissures of hoof wall)

Sole abscess

Sole bruise; puncture wounds

Sole ulcers

Traumatic gonitis

Vertical fissure of hoof wall (sand crack)

3.2.8.2.2

Less Common Causes

Caprine arthritis encephalomyelitis (C)

Chlamydial polyarthritis (O, C)

Coxofemoral luxation

Digital tenosynovitis

Mycoplasma polyarthritis (O, C)

Rupture of cranial cruciate ligament

Septic arthritis

Septic navicular bursitis

Upward fixation of the patella

3.2.8.2.3 Uncommon Causes

Bone or physeal abscess

Bicipital bursitis

Fescue foot

Fractures

Neoplasia

Peripheral nerve paralyses

Sacroiliac luxation

Toxins and plant poisonings

C, Caprine; *O,* ovine.

3.2.8.3 Box 3-7 Causes of Neck and Back Pain in the Horse

3.2.8.3.1 Common Causes

Exertional rhabdomyolysis

Fractures of dorsal spinous processes

Ligamentous strain

Muscular damage

Overriding dorsal spinous processes

Thrombophlebitis

3.2.8.3.2 Less Common Causes

Fracture of the cervical vertebrae

Meningitis

Ossifying spondylosis

Postanesthetic myopathy

Tetanus

3.2.8.3.3 Uncommon Causes

Clostridial myopathy

Congenital defects

Renal pain (acute pyelonephritis, renal calculus)

White muscle disease

3.2.8.4 Box 3-8 Causes of Pain in the Neck and Back in Ruminants

3.2.8.4.1 Common Causes

Meningitis

Muscle injury

Tuber coxae fractures

Urolithiasis

Vertebral and sacral fractures

White muscle disease

Vertebral and spinal abscess

3.2.8.4.2

Less Common Causes

Bladder calculus

Clostridial myopathy

Pharyngeal abscess

Renal pain (acute pyelonephritis or renal calculus)

Ruptured or ulcerated esophagus

Sacroiliac subluxation

Tetanus

Thrombophlebitis

Vertebral neoplasia

Neck pain is frequently manifested by splinting and unwillingness to eat from the ground or assume any but the most benign neck position. Trauma is the most common cause, but meningitis may also cause severe neck pain.

3.2.9

Approach to Diagnosis of Pain on Urination

Although the term *dysuria* means difficult urination, its use has become synonymous with pain on urination. The painful impulses may arise from distention of the wall of the urethra, bladder, or pelvis of the kidney or irritation or spasm of the urethra. The most common causes of dysuria are inflammatory or obstructive conditions involving the urethra (Boxes 3-9 and 3-10). Thus, care must be exercised to identify uroliths, strictures, urethritis, vaginitis,

neoplasia, or fractures involving the pelvic bones. Because urethritis may coexist with other inflammatory conditions involving the urinary tract (e.g., cystitis, pyelonephritis), the diagnostic plan should include physical and laboratory assessments of the kidneys, ureters, and bladder. Urine should be collected for urinalysis, culture, and sensitivity testing. A rectal examination should be performed to detect vesical calculi, tumors, and alterations in the architecture of the kidneys or the size of the ureters. In many cases ultrasonography will be used to evaluate the kidney. Because the severity of pain can resemble that associated with acute abdominal obstruction, the physical examination must be thorough.

3.2.9.1 Box 3-9 Causes of Pain on Urination in the Horse

3.2.9.1.1 Common Causes

- Bladder calculus
- Ruptured bladder

3.2.9.1.2 Less Common Causes

- Cystitis
- Neoplasia
- Urethritis
- Urethral calculi
- Vaginitis

3.2.9.1.3 Uncommon Causes

- Pelvic fracture
- Urethral strictures

3.2.9.2 Box 3-10 Causes of Pain on Urination in Ruminants

3.2.9.2.1 Common Cause

- Urolithiasis

3.2.9.2.2

Less Common Causes

Cystitis

Prolapsed prepuce

Pyelonephritis

Preputial injury or infection

Vaginitis

Urolithiasis occurs more commonly in ruminants than in horses. Of the ruminants, young feedlot steers less than 18 months of age and male sheep and goats (intact or castrated) appear to be at the highest risk. There is an association among sorghum feeds, diets high in magnesium, and the development of the condition. In horses, urinary calculi occur most commonly in geldings, and straining to urinate is the most common clinical sign. Rectal examination of the bladder, endoscopic examination of the urethra, and urinalysis are important aspects of the diagnostic plan. Most calculi in horses are rough, calcium carbonate stones, whereas most calculi in ruminants are magnesium ammonium phosphate, calcium phosphate, carbonate, or silicate in composition (see Chapter 32). Rupture of the bladder, the urethra, or occasionally the ureter may occur secondary to the obstruction.

Straining to urinate is a common clinical sign in newborn foals with a ruptured bladder. This condition generally occurs after the first 24 hours of life, occurs most commonly in males, and involves the dorsal aspect of the bladder. Presumably the rupture occurs during parturition. The diagnosis is facilitated by comparison of creatinine concentration in the blood and peritoneal fluid and by determination of serum electrolyte status. Most foals with the condition are hyperkalemic, hyponatremic, and hypochloremic.

4 Chapter 4 Alterations in Body Temperature

Susan L. White

4.1 CONTROL OF BODY TEMPERATURE

Mammalian species maintain core body temperature within a narrow range despite extremes in environmental conditions. Core body temperature is not constant but exhibits diurnal variation. The normal range of temperature for individuals within a species may vary by as much as 1° C (2° F).

Maintenance of body temperature is under neuronal control in a negative feedback system. Warm- and cold-sensitive neurons within the hypothalamus sense existing core body temperature via peripheral nerve receptors and blood bathing the hypothalamus. Integrative structures located in the preoptic region of the anterior hypothalamus (POAH) that act similarly to a thermostat with a desired "set point" recognize temperatures as either too low or too high and activate both behavioral and autonomic effector responses to either lose or gain heat (Fig. 4-1).[1]

Heat production occurs primarily from muscle activity, which can vary according to need. Muscle activity may range from inapparent contractions to generalized shivering. Digestion of food also contributes significantly to total body heat and may be clinically important as a means of heat production in ruminants both in low environmental temperatures and in high temperatures when the threshold for heat stroke may be lowered. Heat conservation occurs from adrenergic autonomic stimuli to decrease peripheral circulation and cause piloerection. Behavioral means of heat conservation include adopting a "huddled" posture, group aggregation, and seeking a sheltered environment.

Heat loss occurs from conduction, convection, and radiation from body surfaces and by evaporation. Sympathetic vasodilation of cutaneous vessels contributes to surface cooling. As ambient temperature rises, evaporative heat loss becomes more important. In ruminants evaporative heat loss is confined to the respiratory system; respiratory rate increases concurrently with temperature. In horses, sweating aids evaporative heat loss. Behavioral responses that contribute to heat loss include seeking shade and wind currents and wading into water.

4.2 CONDITIONS OF INCREASED BODY TEMPERATURE

Body temperature disorders in which the core body temperature set point is unaltered can occur from increased heat production, absorption of heat, or impairment of heat loss. Central nervous system disorders that disturb the hypothalamic regulatory center, certain drugs, and metabolic disorders may also cause temperature changes. Phenothiazine tranquilizers are a recognized cause of loss of ability to control body temperature.[2] Erythromycin may induce hyperthermia during hot weather, particularly in foals.[3] Hyperkalemic periodic paralysis of horses has also been associated with episodes of hyperthermia.[4]

4.2.1 Exercise

During sustained exercise, heat production may exceed the ability of heat loss mechanisms, leading to a stable increase in core body temperature proportional to the intensity and duration of exercise. The elevation in temperature often persists for several hours after exercise, but temperature returns to normal with rest as heat loss mechanisms remain activated. Body temperatures during exercise greater than 2° C (4° F) above normal, especially if reached early in exercise, are usually the result of severe environmental conditions and/or failure in

heat loss mechanisms. Peripheral cooling to augment heat loss should be used to lower body temperature, as increases in temperature caused by exercise are unaffected by antipyretic drugs.[2,5,6]

The intense muscular activity associated with generalized tonic clonic seizures may, like vigorous exercise, cause a rise in body temperature. If central heat regulatory systems are unaffected by the disease process, body temperatures return to normal no longer than 48 hours after the last seizure.[7] Elevated temperatures that persist for longer periods should prompt investigation into other causes for the increased temperature.

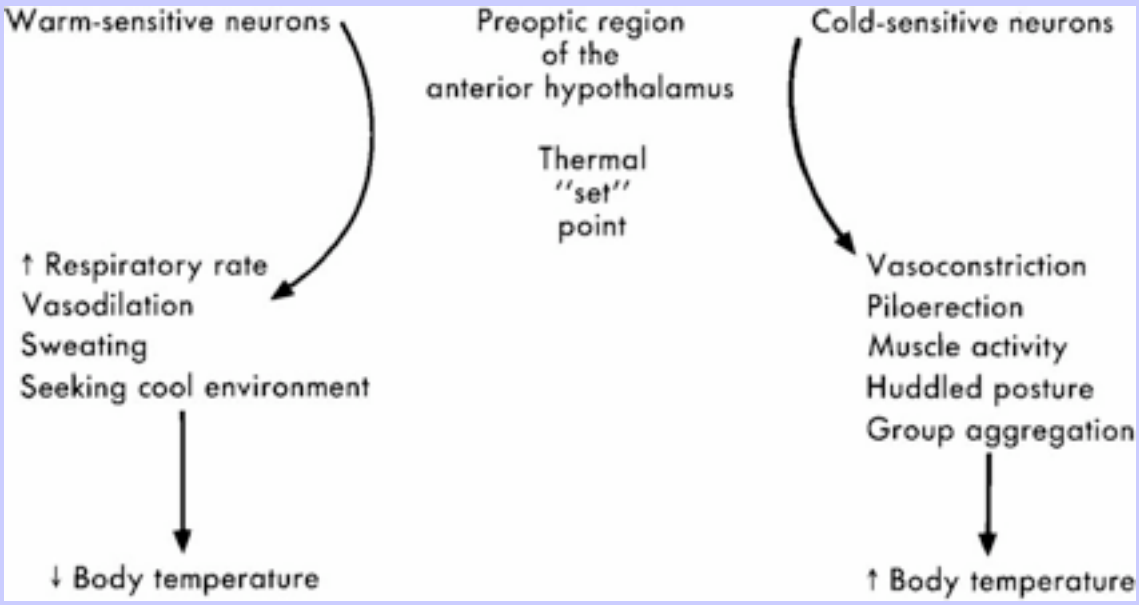
4.2.2 Malignant Hyperthermia

Malignant hyperthermia consists of a group of inherited skeletal muscle calcium metabolism disorders in which a hypermetabolic state of muscle is induced by the administration of halogenated inhalation anesthetics, depolarizing skeletal muscle relaxants, or, occasionally, local anesthetics. Although malignant hyperthermia is most common in humans and pigs, it has been reported in horses.[8–11] Mutation of the ryanodine receptor 1 gene, which is essential in skeletal muscle excitation-contraction coupling, is the basis of malignant hyperthermia in humans, pigs, and dogs. Mutation of this gene has been documented in two horses with malignant hyperthermia.[12] Rapid increase in core body temperature (39° C to 42° C), skeletal muscle rigidity, tachycardia, metabolic acidosis, and muscle necrosis may lead to death.

32

33

Fig. 4-1 Regulation of body temperature.



4.2.3 Ergopeptine Alkaloid Toxicosis

Tall fescue infected with the endophyte *Neotyphodium coenophialum* contains vasoactive ergopeptine alkaloids that cause vasoconstriction and reduced blood flow to the skin of ruminants. These alkaloids also induce bronchoconstriction and pulmonary vasoconstriction, which further compromise ruminants' ability to lose heat, especially during hot environmental conditions. Affected animals have a poor appetite and other indications of

poor performance recognized as part of the syndrome of fescue toxicosis or "summer slump."[13] A related endophyte infesting perennial ryegrass has been found to produce a similar hyperthermic condition in the western United States.[14] *Claviceps purpurea* infestations of annual or perennial ryegrass and of cereal grain heads have also been reported to produce a similar hyperthermic syndrome, which may lead to heat prostration and death when ambient temperatures are high.[15–17]

Cattle affected by any of these ergopeptine alkaloids have few to no clinical signs when environmental conditions are cool and heat loss mechanisms are not challenged. It is not yet known, however, if all of the effects of the alkaloids are peripheral or if they may also act within the central nervous system.[13]

4.2.4 Heat Stroke

When animals are exposed to high ambient temperatures, intense solar radiation, and/or high humidity so that heat load increases at a rate faster than heat can be dissipated, heat stroke may develop. Heat stroke is more common in ruminants because of their inability to sweat and thus their diminished evaporative ability for heat loss. Sheep with fleece and large dense cattle are especially prone to heat stroke when denied access to shade or adequate water and/or when physical activity is imposed on them. Rectal temperature will often exceed 41.5° C (107° F), and central body temperature may exceed 44.5° C (112° F). Horses continuously exercised in high heat and humidity may also develop heat stroke. Evaporative heat loss from sweating is the most important means of heat loss as metabolic heat production increases during exercise, especially as ambient temperature and humidity increase.[18] Efficiency of evaporative heat loss diminishes when temperature and humidity are high and there is a significant radiation component resulting from strong sunshine.[19] Horses' susceptibility to heat stroke is enhanced if dehydration and electrolyte imbalances occur because of large losses of sweat (see Exhaustion in Endurance Horses, Chapter 42).

As rectal temperature increases above 41.5° C (107° F), the homeostatic mechanisms of temperature regulation fail; peripheral vasoconstriction, decreased blood pressure, and decreased cardiac output occur. The animals are lethargic and have weak, flaccid muscles; prostration and shock occur rapidly. Disseminated intravascular coagulation, liver damage, renal failure, and myocardial necrosis are frequent complications.

4.2.5 Anhidrosis

As many as 25% of horses in hot, humid environments lose their ability to sweat and subsequently suffer from hyperthermia as a result of impairment of heat loss.[20] Horses in training have been reported to have a higher frequency of anhidrosis, as are horses shipped to hot environments from more temperate regions; however, horses indigenous to hot, humid areas that perform less rigorously or not at all may also develop anhidrosis.[21,22] In addition to hyperthermia, clinical signs are poor performance, total or partial loss of ability to sweat, increased respiratory rates (three to five times normal), and dry, thin hair coats with areas of alopecia (see also Anhidrosis, Chapter 41).

4.2.6 Diseases of the Nervous System

Central nervous system disorders that damage areas of the hypothalamus associated with temperature regulation may lead to either decreases or increases in body temperature, although hypothermia is most common. Hemorrhage, space-occupying masses (abscesses, tumors), infectious or inflammatory diseases, and degenerative disorders have all been implicated in hyperthermia. Central hyperthermia is usually characterized by lack of

diurnal variation, absence of sweating, resistance to antipyretic drugs, and excessive response to external cooling.[1,2]

Certain toxins and drugs may act to increase body temperature by causing an increase in metabolic work (Boxes 4-1 to 4-3). Chlorophenols and nitrophenols, used as herbicides and wood preservatives, cause uncoupling of oxidative phosphorylation within mitochondria and lead to rapid extreme rises in body temperature.[23] Chronic and/or low-level exposure to these compounds may manifest clinically as hyperthermia.

4.3 FEVER

True fever differs from other hyperthermic states in that the desired core body temperature or set point is elevated. This new, higher set point is vigorously defended by the same mechanisms that maintain body temperature in health. Initiation of the febrile state can occur by a variety of infectious, inflammatory, immunologic, neoplastic, or injurious conditions. In the classic model of fever these stimuli cause the production of multifunctional pyrogenic cytokines by a wide variety of cells, but primarily by fixed or circulating monocytes and macrophages (Fig. 4-2). Currently at least 11 cytokines have been shown to induce the febrile response in humans and animals. Of these cytokines, interleukin 1 (IL-1α, IL-1β) and tumor necrosis factor alpha (TNF-α) are the most potent. Each of these cytokines induces others and stimulates the production of other pyrogenic cytokines (IL-6, interferon [IFN-α, IFN-β, IFN-γ], ciliary neurotropic factor [CNF], and IL-11) that signal cells through a common receptor (glycoprotein 130). Pyrogenic cytokines reach the POAH via the circulation and attach to receptors on the endothelium of the capillaries of the circumventricular vascular organs (CVVOs), which induce the production of arachidonic acid and its metabolism to prostaglandin E_2 (PGE_2), by the cyclooxygenase (COX)-2 pathway. PGE_2, produced on the brain side of the CVVOs, binds to PGE_2 type 3 receptors of glial cells and possibly neuronal cells to initiate neuronal signaling by producing a cascade of changes in cyclic nucleotides, calcium, and neurotransmitters that result in a higher "set point" within the hypothalamic thermoregulatory center[24,25] (see Fig. 4-2). COX inhibitors, and specifically COX-2 inhibitors, effectively reduce the febrile temperature to normal but have no effect on normal body temperature.[2,25]

Box 4-1 Drugs Associated with Fever

FREQUENTLY

Penicillins

Sulfonamides

Erythromycin

Antihistamines

Procainamide

Quinidine

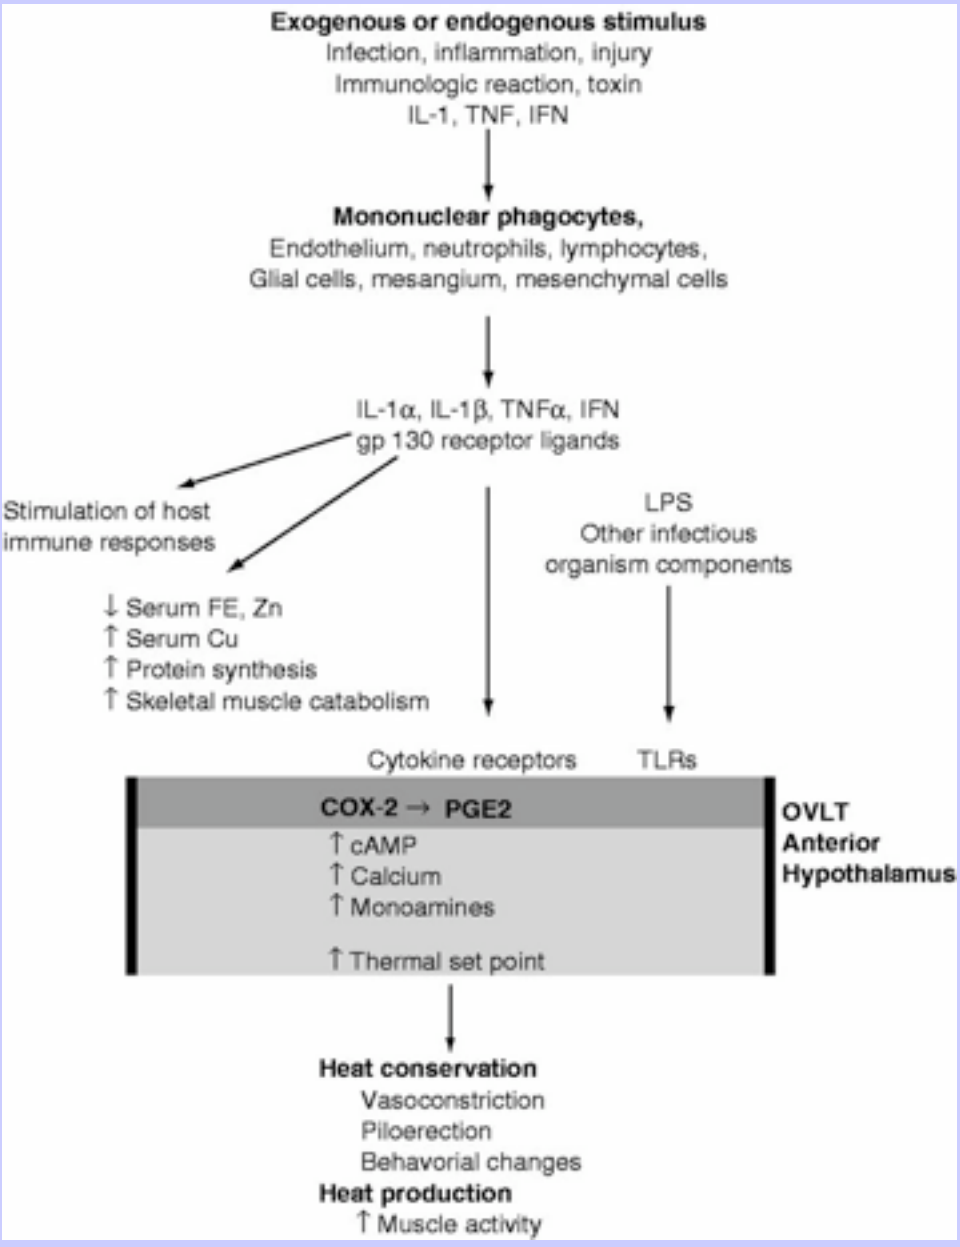
B, Bovine; *C,* caprine; *O,* ovine.

Fig. 4-2 Pathogenesis of fever. *OVLT,* Organum vasculosum laminae terminalis endothelium; *TLRs,* toll-like receptors.



This model, however, does not fully explain the presence of fever, because specific blockade of IL-1 or TNF-α activity does not diminish the febrile response to lipopolysaccharide (LPS) or other microbial products in experimental studies or in patients with natural infections. Microbial products from a variety of agents bind to toll-like receptors (TLRs) on the surface of cells. Toll-like receptors and IL-1 receptors share the same signaling areas and, along with other pyrogenic cytokines, a common pathway to activate nuclear factor (NF)–κB. Activated NF-κB in turn results in expression of COX-2 or COX-3 and PGE_2 synthesis. Mice deficient in COX-2 and injected with LPS, IL-1, TNF-α, or IL-6 either intravenously or within the central nervous system do not develop a fever.[25] Thus the induction of COX-2 and the subsequent production of PGE_2 provide a common pathway for divergent pyrogens to produce the febrile response (see Fig. 4-2).

There is an apparent role for the vagal nerve in the production of the febrile response. Studies in laboratory animals in which the hepatic branch of the vagus nerve is severed have shown diminution of the febrile response to a relatively low dose of intraperitoneally injected LPS but not intramuscularly administered LPS or high-dose intraperitoneally injected LPS. Local production of cytokines may stimulate primary hepatic vagal receptors that, via vagal afferent fibers and A1/A2 noradrenergic cell groups in the brainstem, release noradrenaline, which subsequently induces the production of PGE_2 and fever.[26]

In addition to a rise in body temperature, the febrile state is accompanied by a variety of metabolic, hematologic, and immunologic changes. IL-6 and IL-11, induced by IL-1α, IL-1β, and TNF-α, induce the synthesis of fibrinogen, C-reactive protein, haptoglobin, ceruloplasmin, and certain macroglobulins, known collectively as *acute phase proteins,* by hepatocytes. In addition, these cytokines mediate the accompanying hypoferremia, hypozincemia, and hypercupremia of the acute phase response. Pyrogenic cytokines stimulate the activation and proliferation of T-lymphocytes and of antibody-producing B lymphocytes which, in turn, produce additional cytokines that both enhance and inhibit further production of pyrogenic cytokines.[27,28] Pyrogenic cytokines, particularly IL-1 and TNF-α, cause membrane perturbation in a variety of body tissues, with a resultant increase in phospholipases and the production of arachidonic acid. Subsequent production of mediators is dependent on the metabolic pathways for arachidonic acid in the target tissue. Prostaglandins induced by pyrogenic cytokines have been shown to stimulate the muscle catabolism associated with fever and to induce collagenase synthesis from synovial cells.[29] These processes contribute to the muscle and joint pain associated with fevers that are relieved by COX inhibitors. Lymphocyte and granulocyte response to IL-1 has been shown to be blocked by inhibitors of lipoxygenase but unaffected by indomethacin.[27] Local tissue responses to IL-1β and TNF-α may stimulate afferent neural impulses that are responsible for many of the behavioral changes (increased sleep, decreased appetite, and loss of social behavior) associated with fever. Transection of the visceral vagal afferents has been shown to attenuate febrile behavioral responses, but not the associated temperature elevation, to high-dose intraperitoneal LPS injection in rats.[30]

Physiologic control of the febrile response is multifactorial and prevents extreme elevations in body temperature that are incompatible with life in most instances. TNF-α inhibits further production of itself. IL-1 and other inhibitory cytokines stimulate the production of IL-1 receptor agonist, which prevents further binding of IL-1. In addition, one of the receptors on cell surfaces for IL-1 (type II receptor) does not result in cell signaling and is thought to serve as a "decoy" receptor to decrease the concentration of IL-1.[31] IL-10, induced by pyrogenic cytokines, inhibits IL-1, TNF, and IL-6 production and suppresses the production of IL-2 and IFN-γ by T-helper cells.[31,32] Circulating pyrogenic cytokines may be bound to carrier molecules that reduce or prevent the interaction with receptors. For example, IL-1β has been shown to bind to α_2-macroglobulin, a protein increased during the acute phase response.[1] Glucocorticoids inhibit the transcription of numerous genes encoding the pyrogenic cytokines IL-1β, Il-6, and TNF-

α. Within the brain both arginine vasopressin (AVP) and alpha melanocyte stimulating hormone (αMSH) act as potent antipyretic agents. Receptors for AVP, which acts as a neurotransmitter within the brain, are found lateral to the PAOH and decrease fever in both natural and experimentally induced fever, whereas injection of AVP receptor antagonist elevates fever and delays defervescence.[33,34] αMSH binds to local melanocortin receptors within the brain and on cell receptors of immune cells to decrease fever and inflammation. When administered systemically to humans, αMSH is 20,000 times more potent on a molar basis than acetaminophen in decreasing fever from endogenous pyrogens.[34] In the brain, nitric oxide (NO), by activating soluble guanylate cyclase and increasing cyclic guanosine monophosphate (cGMP) levels, participates in regulation of body temperature. Intracerebral ventricular injection of NO donors depresses fever in rats, whereas inhibition of NO synthesis within the central nervous system enhances fever.[31]

In summary, the occurrence of fever during disease results from a complex interaction of multiple cytokines and microbial products that act locally (site of tissue injury), systemically (in the circulation) and in the POAH of the brain and affect the immune, endocrine, and nervous systems.

4.3.4 Beneficial Effects of Fever

Body temperature elevation in pyrogenic mediated fevers, in contrast to hyperthermic states, rarely exceeds 2.5° C (5° F) above normal. Although the severity of some viral infections is decreased at these temperatures, most pathogens are not affected by a modest rise in temperature. Studies on bacterial infections in fish, lizards, rabbits, and humans, however, have shown an increase in survival correlated with the presence of fever.[2,35,36] One well-studied effect of fever on bacterial proliferation is the effect of hypoferremia. Bacteria, which require iron for multiplication, are inhibited by the reduced availability of iron during the acute phase reaction. This response is augmented by the increased susceptibility of bacteria to low iron at higher temperatures.[37,38] Certain neoplastic cells are inhibited during fever, although it is likely that inhibition of neoplastic cell division results from augmentation of immune responses.

35
36

Literature on the effect of fever is conflicting owing to the multiple variables present in in vivo studies and the application of heat in temperature ranges exceeding those of natural fevers in in vitro studies. Enhancement of host defenses, however, appears to be the primary beneficial effect of fever. Fever or heat applied in in vitro studies within the physiologic range of natural fevers has a beneficial effect on multiple processes of the adaptive immune response. Neutrophils and monocytes have increased motility and emigration, enhanced phagocytosis, increased oxygen radical production, and enhanced killing of intracellular bacteria. IFN production increases, and its antiviral, antitumor, antiproliferative, and natural killer (NK) cell—stimulating properties are enhanced. Increased T-cell proliferative responses to nonspecific mitogens IL-1 and IL-2, and enhanced T-helper cell activation, expression, recruitment, and cytotoxicity have all been correlated with fever. Enhancement of B cells, with a subsequent increase in production of antibodies, and enhanced expression of Fc receptors occur during fever.[39]

Activity of pyrogenic cytokines is also influenced by temperatures achieved during fever. For example, in a mouse-endotoxin model, fever enhanced the early expression of TNF-α but limited the duration of its expression. Production of IL-1β was delayed, whereas that of IL-6 (which downregulates production of TNF-α and IL-1β) was enhanced, preventing the simultaneous expression of TNF-α and IL-1β and the potential harmful effects of their simultaneous expression.[40] Other studies have demonstrated that the effect of fever on various cytokines is specific for each cytokine and specific to body compartments. Thus fever is an important component of the coordinated and specific cytokine response of the host to various inflammatory stimuli.[1,28,39]

4.3.5

Adverse Effects of Fever

The beneficial effects of fever during bacterial infections in rabbits have been shown to reverse at temperatures greater than 3° C (5° F) above normal. Cytokine disregulation may result in prolonged or extreme fevers with adverse effects on a variety of body functions in addition to the immune response. Catabolic metabolic processes during fever are markedly different from catabolism of starvation. Protein loss occurs four times as rapidly in individuals with infectious or inflammatory diseases as compared with starvation-adapted individuals. Ketonemia is inhibited, resulting in the oxidation of large amounts of muscle-derived amino acids for energy. This cytokine-driven catabolism, combined with the decreased feeding behavior that accompanies fever, variable anorexia (even if feed is provided), and increased metabolic rate at higher temperatures, can result in rapid and severe muscle wasting, weakness, and atrophy. In humans high fevers frequently cause seizures, especially in children,[2] but this is rare in animals unless temperatures reach 42° C (108° F) in neonates. Prolonged high fevers in debilitated animals may lead to failure of the cardiovascular system.

Fever is one of the earliest and most prominent manifestations of the acute phase reaction. Veterinarians have used the clinical thermometer to aid in diagnosis and to monitor the progress of illness in animals since 1770. With the increased knowledge of the pathogenesis of fever has come a better appreciation for the diverse causes of the febrile state. In ruminants and horses, however, infectious disease remains the most common reason for development of fever (Boxes 4-4 and 4-5). Careful evaluation for the presence of infectious disease is always indicated, especially when the onset of a fever is abrupt; the temperature is >39.4° C (103° F); and the fever is accompanied by depression, variable loss of appetite, serous nasal exudate, epiphora, enlargement of lymph nodes, or diarrhea and a decreased or increased leukocyte count. Other causes of fever are neoplasia (Boxes 4-6 and 4-7), immune-mediated diseases (Boxes 4-8 and 4-9), noninfectious inflammation (Boxes 4-10 and 4-11), and certain drugs.

4.3.5.1

Box 4-4 Infectious Causes of Fever in Horses

4.3.5.1.1

COMMON CAUSES

Upper respiratory viral diseases

Strangles, *Streptococci equi*

Pneumonia, bacterial or viral

Pleuropneumonia

Gastrointestinal parasitic infections

Enteritis, *Clostridium difficile, Lawsonia,* or of unknown causes

Salmonellosis

Equine monocytic ehrlichiosis (Potomac horse fever)

Proximal duodenitis-jejunitis

Rotavirus diarrhea (foals)

Endotoxemia from gastrointestinal disorders

Septicemia, septic arthritis, osteomyelitis (foals)

Urachal abscess (foals)

Metritis (mares)

Peritonitis

Tetanus

Traumatic tenosynovitis, cellulitis

Localized occult abscesses (thorax, abdomen, upper respiratory system)

Tumors (see list in Box 4-6)

4.3.5.1.2

LESS COMMON CAUSES

Equine encephalomyelitis (EEE, WEE)

West Nile virus

Osteomyelitis (adults)

Vesicular stomatitis

Tyzzer's disease (foals)

Malignant edema

Bacterial endocarditis

Mastitis

Pyelonephritis

Equine infectious anemia

Equine viral arteritis

Otitis media and interna

4.3.5.1.3

UNCOMMON CAUSES

Pericarditis

Systemic or pneumonic aspergillosis, candidiasis

Pneumocystis carinii

Brucellosis

Tularemia

Anthrax

Rabies

Lyme disease *(Borrelia burgdorferi)*

Nocardiosis

Coccidioidomycosis

Babesiosis, piroplasmosis

Toxoplasmosis

EEE, Eastern equine encephalitis; *WEE,* western equine encephalitis.

4.4 FEVERS OF UNKNOWN ORIGIN

Most febrile illnesses encountered in large animal practice are caused by infectious diseases that are readily diagnosed by careful evaluation of history and physical examination or are of short duration, run their course, and progress to complete recovery within 2 weeks without a specific etiologic diagnosis having been made. Some febrile conditions, however, continue for weeks or months, accompanied only by nonspecific signs of depression, variable anorexia, and weight loss, while the diagnosis remains obscure. Patients with prolonged febrile episodes of 3 weeks' duration or longer in which a diagnosis has not been made after a week of routine diagnostic efforts or after 3 days of hospitalization and diagnostic tests are considered to have fever of unknown origin (FUO). The majority of cases that meet the definition of FUO have infectious causes. Neoplastic diseases, immune-mediated vasculitides, and autoimmune diseases are the next most common causes. Adverse drug reactions and other miscellaneous diagnoses are the least common documented causes of FUO. Most cases of FUO are caused by common diseases with an unusual presentation; an ordered, problem-oriented approach to diagnosis will render a diagnosis in 90% of cases.[37,41] The following steps are suggested (Fig. 4-3).

4.4.1 Box 4-5 Infectious Causes of Fever in Ruminants

4.4.1.1 COMMON CAUSES

Mastitis

Metritis

Pneumonia: viral, mycoplasma, bacterial

Traumatic reticuloperitonitis (B)

Leptospirosis

Septicemia, osteomyelitis, infectious arthritis, omphalophlebitis (neonates)

Toxemia from gastrointestinal disorders

Enteritis

Abscesses

Pharyngeal

Internal lymph nodes (C, O)

Associated with foot

Verminous pneumonia (B)

Listerosis

Bovine viral diarrhea (BVD), mucosal disease (B)

Otitis media, interna

Balanoposthitis (O)

Clostridial infections

Blackleg *(Clostridium chauvoei)*

Clostridium perfringens types D, A (C, O)

Anaplasmosis

Contagious ecthyma (C, O)

Haemophilus somnus infection (thromboembolic meningoencephalomyelitis)

Mycoplasma species arthritis, septicemia (C)

4.4.1.2 LESS COMMON CAUSES

Endocarditis

Pericarditis (B)

Bluetongue (O)

Tetanus

Vesicular stomatitis

Malignant catarrhal fever (B)

Verminous pneumonia (C, O)

Cystitis, pyelonephritis

Epididymitis (C, O)

Chlamydial abortion

Enzootic abortion (C, O)

Epizootic abortion (B)

Caprine arthritis encephalomyelitis (C)

Hoof abscess, footrot

4.4.1.3 UNCOMMON CAUSES

Neoplasms (see list in Box 4-7)

Rabies

Infectious necrotic hepatitis *(Clostridium novyi)*

Sarcocystosis (B)

Tuberculosis (B)

Systemic candidiasis, aspergillosis

Eperythrozoonosis

Brainstem, pituitary abscess

Systemic toxoplasmosis (C, O)

Tularemia

Pseudorabies

Brucellosis

Ovine progressive pneumonia

Chlamydial sporadic bovine encephalomyelitis

B, Bovine; *C,* caprine; *O,* ovine.

UNCOMMON CAUSE

Pemphigus foliaceus (C)

B, Bovine; *C,* caprine.

4.4.6

Box 4-10 Noninfectious Inflammatory and Miscellaneous Causes of Fever in Horses

Hepatic disorders

Hyperlipidemia, equine hepatic lipidosis

Acute hepatic necrosis (Theiler's disease)

Chronic active hepatitis

Cholelithiasis

Hyperkalemic periodic paralysis

Foreign bodies

Nasal, oral, pharyngeal, tracheal, bronchial

Thrombophlebitis

Ocular trauma, recurrent uveitis

Burns, smoke inhalation

Snake bite

Acute renal failure

Idiopathic interstitial pneumonia

4.4.7

Box 4-11 Noninfectious Inflammatory and Miscellaneous Causes of Fever in the Ruminant

Phlebitis, thrombophlebitis

Salt toxicity, water deprivation

Acute bovine pulmonary emphysema

Fat necrosis (B)

Burn, smoke inhalation

Ocular trauma

Snake bite

Acute renal failure

Primary photosensitization

Cholelithiasis (B)

Postparturient hemoglobinuria (B)

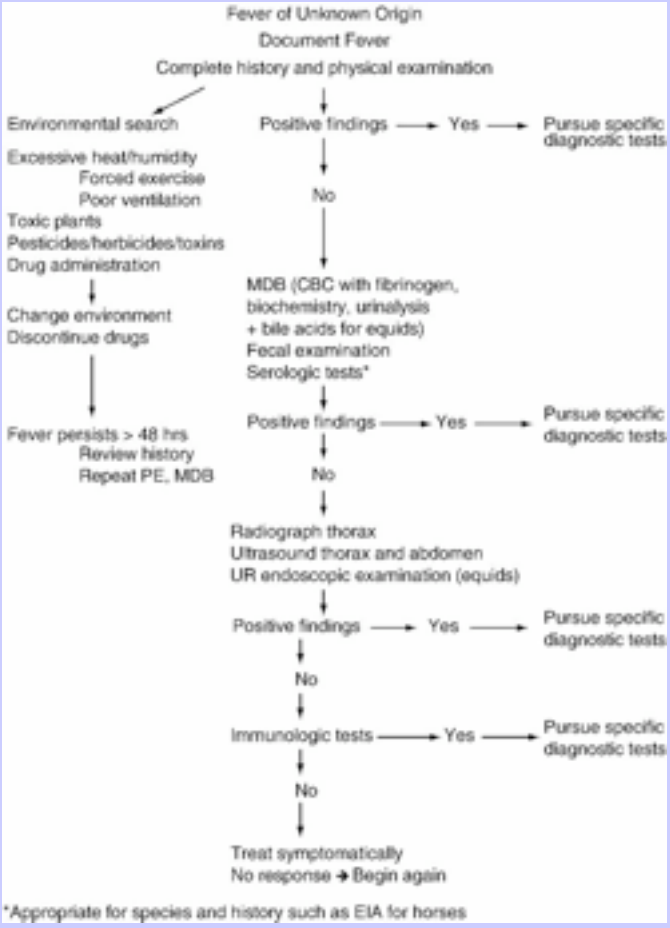
B, Bovine.

4.4.8

Document Fever

A temperature chart consisting of at least twice daily determination of rectal temperature should be completed to characterize the fever pattern. *Intermittent fevers* are characterized by diurnal variation in which a peak elevation of temperature of >0.75° C (1.5° F) occurs, followed by a decline in temperature, which in some patients falls within the normal range. Most intermittent fevers peak in late afternoon or evening, with the lowest temperatures occurring in the morning; but approximately 10% of cases will have a reverse pattern. Intermittent fever is most commonly associated with pyrogenic infections, although it may occur in neoplasia, especially if tissue necrosis and inflammation are concurrent. *Remittent fevers* are characterized by a period of days in which elevated temperatures occur, followed by several days of normal temperature, only to have the cycle repeat again. Brucellosis in ruminants, equine infectious anemia (EIA) in horses, and blood-borne protozoal diseases such as babesiosis may exhibit this type of pattern. *Sustained fevers* are characterized by a consistently raised temperature without variation and appear as a "flat line" on a temperature chart. Fevers caused by drug administration and certain toxins may be of this type, especially if the patient does not exhibit any other signs of illness.[2] Any pharmacologic agents being administered to the patient should be discontinued. Defervescence of fever from drug administration should occur in 48 hours.

Fig. 4-3 Approach to fever of unknown origin (FUO).



4.4.9 Consideration of Epidemiology

Repeated efforts to obtain a complete history in chronologic order of development of clinical signs may be necessary to extract all the information pertaining to the individual animal. A knowledge of forage available, presence of nutrient deficiencies and excesses, toxic plants, and infectious organisms indigenous to the area, as well as the threat of exotic diseases, is necessary for the present and past geographic environment of the animal.

4.4.10 Physical Examination

A physical examination (see Chapter 1 and Chapter 2) should be carefully performed to evaluate all body systems as thoroughly as possible and repeated as often as practical, because it is unusual for a disease to cause a prolonged fever without the occurrence of some physical signs. Examination should include the following:

1 Horses

- a Complete visual or manual oral examination; percussion of sinuses; endoscopic examination of upper airway structures and of the trachea and bronchi (if length of the endoscope allows)
- b Complete ophthalmic examination
- c Thorough auscultation of cardiopulmonary system at rest, with rebreathing bag, and following exercise; evaluation of peripheral perfusion before and after exercise
- d Palpation of external lymph nodes, ballottement, and deep palpation of external abdomen for pain
- e Rectal examination
- f Fecal odor, consistency, volume; frequency of defecation
- g Evaluation of external genitalia and mammary gland
- h Evaluation of musculoskeletal conformation and gait analysis for lameness

2 Ruminants

- a Complete visual or manual oral examination; percussion of sinuses
- b Complete ophthalmic examination
- c Thorough auscultation of cardiopulmonary system, evaluation of peripheral perfusion
- d Palpation of all external lymph nodes
- e Rate and quality of rumen contractions, abdominal ping, and ballottement for rumen fill and pain
- f Fecal color, consistency, volume; frequency of defecation
- g Complete udder examination and milk evaluation of lactating females
- h Testicular and penile palpation of males

i Complete rectal examination (cattle)

j Evaluation of musculoskeletal conformation and gait analysis for lameness

4.4.11 Diagnostic Aids (Table 4-1)

All cases of FUO should have a laboratory database consisting of a complete blood count (CBC), urinalysis, and biochemical profile. The CBC should include morphology of red blood cells and white blood cells (WBCs), WBC differential, and fibrinogen determination. Chronic inflammatory disease produces characteristic changes in the CBC (see Chapter 24 and Chapter 26), and morphologic evaluation of the blood smear may reveal blood-borne parasites.

Serum protein and albumin determinations characterize either hypoproteinemia or hyperproteinemia. Serum protein electrophoresis and immunoelectrophoresis further classify deficiencies or increased production of proteins. Serum enzyme determinations and bile acid concentration for liver evaluation are also warranted.

Because much of the abdomen is unavailable to rectal palpation, abdominocentesis and evaluation of peritoneal fluid for protein, cellularity, and cell morphology are justified. Peritoneal fluid is obtained more consistently in horses than in ruminants with abdominal disease because of the presence of the greater omentum and the rapid formation of fibrinous adhesions in ruminants with inflammatory abdominal disease. Peritoneal fluid evaluation is usually most helpful in inflammatory diseases, but it may be diagnostic in some cases of abdominal neoplasia. Bacterial culture and sensitivity of peritoneal fluid are indicated in inflammatory diseases when WBCs show degenerative or toxic changes but are rarely positive unless gross bowel contamination has occurred. Polymerase chain reaction (PCR) for *Streptococcus equi* and/or *Rhodococcus equi* may be warranted in horses with evidence of chronic inflammation of the abdominal cavity.

Blood cultures are best used after characterization of a remittent fever and evidence of pyogenic inflammatory disease from the laboratory database. Any antimicrobial therapy should be discontinued 48 to 72 hours before sampling. Three to five samples should be collected at least 45 minutes apart and are best taken directly into culture media. Sampling just before and during a temperature rise is more likely to yield positive results than sampling at the temperature peak and decline.

Serologic evaluation for infectious diseases common in the geographic area and/or patient population should be performed. Single serologic determinations usually are of value only in those diseases in which one positive titer is significant and when the disease is characterized by persistent infection such as EIA, brucellosis, or Johne's disease. In many instances vaccination history and/or accompanying clinical signs must be correlated with titer determinations. Paired samples for toxoplasmosis, babesiosis, and various mycotic diseases (especially coccidioidomycosis) are indicated when the diagnosis remains obscure. Serologic determination of antibody titers to the SeM protein of *S. equi* can aid in the diagnosis of internal abscessation.[42] Virus isolation and/or PCR, particularly in persistent bovine viral diarrhea (BVD)–infected cattle, may be helpful.

Evidence of gastrointestinal protein loss, chronic diarrhea, or persistent melena warrants several fecal or rectal biopsy cultures for salmonella in horses and calves, whereas such signs in adult dairy cattle warrant ruling out bovine leukosis as the cause.

Also helpful are biopsies of enlarged lymph nodes, accessible abdominal masses, and the liver and kidney when laboratory data indicate abnormalities. Liver biopsies should be cultured and evaluated histologically, because bacterial cholangiohepatitis can be a cause of FUO. Evaluation of biopsies for the presence of immunoglobulins,

particularly if skin lesions are present, may add in diagnosis of immune-mediated disorders. Antinuclear antibody determinations and a Coombs' test are also indicated in suspected immune-mediated diseases.

Radiographic evaluation, particularly of the thorax, should be performed in horses and small ruminants and is often possible in dairy cattle. Ultrasonographic examination of the heart may definitively diagnose cardiac abnormalities and may provide more complete scrutiny of other organs in the thorax and abdomen, as well as deep structures of the musculoskeletal system. Ultrasonographic examination also aids in percutaneous biopsy of internal structures and may help the practitioner make the decision for exploratory laparotomy. 39

Table 4-1 Fever of Unknown Origin: Diagnostic Procedures

Procedure	Indications
Abdominocentesis	Abdominal pain Abnormal rectal examination (e.g., mass) Fluid wave on ballottement or ultrasonography
Biopsy	Enlarged lymph nodes or other mass found Abnormal renal or liver function test results Vesicular or ulcerative skin lesions
Blood culture	Intermittent fever, especially in a neonate with failure of passive transfer Neutropenia or neutrophilia ± bands Increased fibrinogen Cardiac murmurs (bacterial endocarditis)
Radiography	Any musculoskeletal pain, heat, swelling Thorax, see transtracheal aspirate
Synovial fluid aspirate	Joint effusion, heat, pain
Thoracocentesis	Abnormal percussion of chest Fluid line thoracic radiographs Fluid found on ultrasonography
Transtracheal aspirate	Persistent cough or nasal exudate with normal upper respiratory tract Abnormal auscultation or percussion of thorax Persistent increased respiratory rate
Bronchial alveolar lavage	Exercise intolerance with normal cardiovascular system
Immunodiagnostic screening	
Serum protein electrophoresis	Abnormal serum protein
Serum protein immunoelectrophoresis	Hypergammaglobulinemia Hypogammaglobulinemia (horses)
Direct Coombs' test	Hemolytic anemia RBC autoagglutination
Skin biopsy direct immunofluorescence	Vasculitis, purpura Bullous or ulcerative skin lesions
Antinuclear antibody	Multiple noninfectious arthritis
ECG	Dysrhythmia, congestive heart failure
Bone marrow aspiration	Anemia Thrombocytopenia
Gastrointestinal absorptive tests (horse)	Hypoproteinemia with normal kidney, liver
Serology	Persistent undiagnosed disease
Exploratory laparotomy	Abnormal rectal examination, ultrasonography Chronic abdominal pain Abnormal peritoneal fluid
Ultrasonography	Cardiac murmurs, dysrhythmias Abnormal liver or kidney function tests Abdominal mass Suspect fluid in thorax, pericardium, abdomen

ECG, Electrocardiogram; *RBC,* red blood cell.

Exploratory laparotomy without direct evidence of abdominal disease should be performed only in patients that are becoming progressively debilitated and in which all other avenues of diagnosis have been exhausted. Blind exploratory laparotomies usually do not contribute to diagnosis, are costly, and are not without risk. Exploratory laparotomy is used for diagnostic purposes more routinely in ruminants than in horses.

Nuclear imaging and imaging using autologous WBCs labeled with technetium-99m or indium-111 are increasingly used in human and small animal medicine.[43] These procedures may be helpful in localizing abscesses, particularly osteoarticular infections. These modalities may prove to be of benefit for large animals as the modalities' availability increases.

The use of therapeutic trials of antimicrobials in FUO should be restricted to cases in which strong evidence of a bacterial infection exists. The therapeutic regimen should be as specific as possible and administered for a predetermined amount of time. Inappropriate use of broad-spectrum antimicrobials for all febrile diseases contributes to interference in accurate diagnosis.

4.5 HYPOTHERMIA

Decreases in body temperature may occur when environmental stresses (cold, wet, wind) overwhelm the body's capability of heat production (especially when the body is weakened from disease), when central nervous system disease has resulted in damage to the regulatory centers within the hypothalamus, or when adrenergic or sympathetic effector systems have been damaged. Newborns, cachexic, and very aged animals are most susceptible to heat loss caused by cold exposure (see neonatal sepsis and weak calf syndrome, Chapter 20). Concurrent signs of septic disease in hypothermic animals signify a guarded prognosis because the body's defense mechanisms are often overwhelmed when core body temperature declines. Severely hypothermic animals (core body temperature >30° C) 40
are profoundly depressed and have marked reduction in ventilation, absence of muscle activity, and decreased 41
reflexes. Decreased intravascular volume and depressed cardiac function lead to hypoxia, acidemia, and cardiac dysrhythmias. Newborns are often hypoglycemic and have potassium imbalances. These animals should be warmed by protecting them from wind or drafts, drying them, and providing a microenvironment of high ambient temperature. Applying thermal blankets and housing them in an insulated stall, with or without supplemental heat, are superior to direct external heat from heat lamps or other sources. Direct external heat without environmental control causes cutaneous vasodilation, often exacerbates central hypothermia, and contributes to cardiovascular compromise.

Animals with severe hypothermia should be warmed gradually over 24 hours, with careful monitoring of body temperature and the cardiovascular system. Maintenance of adequate systemic perfusion is the most important means of preventing cardiac failure.[44,45] Acidosis and potassium imbalances are common and may fluctuate rapidly. Consequently, repeated measurements, especially when a patient's clinical condition worsens in the process of warming, are often necessary. Appropriate crystalloid fluids, warmed to body temperature, are usually necessary throughout the warming process. Evaluation of blood glucose and concurrent dextrose therapy, especially in neonates, should also be performed.

Warmed humidified oxygen therapy both as an aid in treatment of hypoxia and as a means of warming is helpful. Gastric (rumen) or rectal lavage with warmed fluids may also be used. However, care should be taken in rapid rewarming, because an imbalance in the basal metabolic rate (which is temperature dependent) and systemic perfusion may result in life-threatening cardiac dysrhythmias and worsening of metabolic acidosis and hypoxia. Hypothermia attenuates the inflammatory response by a multiplicity of effects on cytokines and other key signaling mechanisms.[46] Thus the adverse metabolic effects of disease are slowed at low body temperatures, and, as body

temperature elevates, signs of systemic disease become apparent.[47] In hypothermic animals in shock, particularly neonates, severe anoxic changes in the bowel wall may result in severe diarrhea, sloughing of mucosa, or clostridial growth in the bowel.

5 Chapter 5 Alterations in Respiratory Function

W. David Wilson

Consulting Editors

Jeanne Lofstedt

5.1 COUGH

5.1.1 Definition

Coughing, a normal and important respiratory defense mechanism, is the sudden, forceful, noisy expulsion of air through the glottis to clear mucus, particles, and other material from the tracheobronchial tree and glottis.

5.1.2 Pathophysiology

The mucociliary escalator and the cough reflex are the major protective mechanisms that function together to remove material from the respiratory tract.[1,2] Particles trapped in mucus are carried toward the trachea by continuous waves of ciliary motion that start at the level of the terminal bronchioles. Coughing may effectively remove secretions from the tracheobronchial tree proximal to the level of the segmental bronchi.[3]

5.1.2.1 NEURAL PATHWAYS INVOLVED IN THE COUGH REFLEX

Coughing is an involuntary reflex that can also be suppressed or initiated voluntarily.[2,3] The reflex pathway involves sensory receptors of nerve fibers that extend between epithelial cells and ramify throughout the tracheobronchial tree from the level of the larynx to the respiratory bronchioles.[4,5] These receptors, many of which are irritant receptors, are particularly numerous in the trachea and bronchi, especially around the hilus of the lung and at the bifurcation of bronchi.[1,4] Other receptors that can stimulate coughing are found in the lung parenchyma, in the pleura, and in other locations. Myelinated afferent fibers from cough receptors pass predominantly in the vagal, but also in the glossopharyngeal, trigeminal, and phrenic nerves, to the cough center in the medulla oblongata.[1,3,5] Brainstem neuronal pathways for the cough reflex in the horse are not well characterized. Efferent fibers pass in the vagal, phrenic, intercostal, and lumbar nerves and motor portions of the trigeminal, facial, hypoglossal, and accessory nerves to supply the striated and smooth muscles of the larynx, tracheobronchial tree, diaphragm, intercostal muscles, abdominal muscles, and glands of the respiratory tract.[1,5–7]

Irritant receptors are stimulated by mechanical deformation such as that induced by pinching the trachea or by bronchoconstriction, by chemically inert dusts such as carbon, by pollutant gases such as ammonia, by inflammatory conditions, and by chemical mediators such as histamine (Boxes 5-1 and 5-2).[2,4] Sensitivity to mechanical stimulation varies along the airway, and in horses the upper airway cough receptors appear to be less active than in many other species.[8] For example, a stomach tube inadvertently passed into the trachea frequently does not induce coughing until it reaches the bifurcation. Similarly, endoscopic examination often reveals a large pool of exudate in the trachea of horses with little or no history of coughing.[6] Foals with

Rhodococcus equi pneumonia often have a tracheal rattle, reflecting accumulation of tenacious exudate in the trachea, but may not cough. Repeated stimulation of irritant receptors over several hours does not appear to diminish sensitivity but may lead to changes in threshold.[4]

Bronchoconstriction is a constant component of cough,[3,7,8] and stimuli of cough also may induce reflex bronchoconstriction through the parasympathetic nervous system.[4] However, cough and bronchoconstriction are separate airway reflexes.[7] Whereas stimulation of irritant receptors in large airways may induce both cough and reflex bronchoconstriction independently, stimulation of nerve endings in smaller airways does not directly initiate coughing but does cause bronchoconstriction, which may initiate coughing indirectly.[4] The role of bronchoconstriction in the induction of coughing is supported by studies showing that coughing in asthmatic people can be prevented by aerosol administration of salbutamol (a bronchodilator) or of local anesthetics or cromolyn sodium.[9,10] This suggests that mediator release (blocked by cromolyn) causes bronchoconstriction (blocked by bronchodilators), which stimulates irritant receptors (blocked by local anesthetics) and causes coughing.[4] Much of the airflow obstruction in horses with recurrent airway obstruction (RAO) appears to be mediated through these pathways and in many cases can be eliminated with atropine, a parasympatholytic bronchodilator.[4]

5.1.3

Mechanics of Coughing

The mechanical events that produce coughing occur during four phases: inspiration, compression, expression, and relaxation.[2–4] The first three phases are necessary to create the decreased airway cross-sectional area and high airflow rates needed for an effective cough. Coughing is a maximum expiratory flow maneuver that begins with deep inhalation to expand lung volume, increase elastic recoil, and dilate the airways through the tethering effect exerted by surrounding lung tissue.[11] Closure of the glottis is followed by forced expiratory efforts involving the rib cage, abdomen, and diaphragm, which increase pressure in the abdominal, pleural, and alveolar spaces to over 500mm Hg.[4] The glottis then opens suddenly, allowing the elevated alveolar pressure to rapidly accelerate gas flow from the respiratory tree.[2,4,11] This high-velocity gas stream shears exudate from the airway walls and lumen and carries it to the nasopharynx, from which point it exits the respiratory tract as nasal discharge or is swallowed.[11] Airflow stops before the animal has exhaled to residual volume because the glottis closes or the driving force provided by the muscles abates.[4] The characteristic sound of coughing is produced by vibration of laryngeal and pharyngeal tissues, narrowing and deformation of airways, vibration of surrounding lung tissues, and turbulent gas flow vibration in the airway.[4,7]

42

43

5.1.3.1

Box 5-1 Causes of Coughing in Horses

5.1.3.1.1

COMMON CAUSES

Equine influenza A2 virus

Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)

Other viruses (rhinovirus types 1, 2, 3; reovirus)

Bacterial pneumonia

Bacterial pleuropneumonia, pleuritis

Recurrent airway obstruction (RAO or COPD)

Mechanical causes (e.g., nonspecific dust irritation)

Pharyngitis (acute; chronic pharyngeal lymphoid hyperplasia)

Postviral hyperreactive airways

5.1.3.1.2

LESS COMMON CAUSES

Strangles (*Streptococcus equi* infection)

Equine viral arteritis

Parascaris equorum migration

Pharyngeal paresis

Guttural pouch empyema

Guttural pouch mycosis

Pharyngeal, laryngeal trauma or surgery

Postsurgical aspiration (e.g., after laryngeal prosthesis surgery)

Epiglottal entrapment

Subepiglottal cyst or abscess

Chondritis, chondromas of the arytenoid cartilages

Retropharyngeal abscess

Tracheal collapse (including scabbard trachea in ponies)

Tracheal stenosis, stricture

Choke, esophageal obstruction

Aspiration pneumonia (foreign bodies, feed material)

Inhalation pneumonia (smoke, thermal injury, noxious gases)

Lungworm infection *(Dictyocaulus arnfieldi)*

Pulmonary abscessation

Exercise-induced pulmonary hemorrhage (EIPH)

Pulmonary edema (smoke inhalation, acute renal failure, overhydration, septicemia, anaphylaxis)

Summer pasture—associated obstructive airway disease (SPOAD)

Left-sided heart failure

Congestive cardiac failure

Neonatal septicemia

5.1.3.1.3

UNCOMMON CAUSES

Tuberculosis

Pneumoconiosis or silicosis; other interstitial pneumonias

Eosinophilic interstitial pneumonia

Nocardiosis

Coccidioidomycosis

Chlamydia psittaci pneumonia

Mycoplasma species pleuritis

Tularemia

Pulmonary hydatidosis

Tracheal perforation or rupture

Cryptococcosis

Dorsal displacement of the soft palate (laryngopalatal dislocation)

Rostral displacement of the palatopharyngeal arch

Idiopathic laryngeal hemiplegia

Guttural pouch neoplasia

Rectus capitis ventralis muscle rupture

Adenovirus infection

Pneumocystis carinii pneumonia

Esophageal ectasia, dysfunction, stricture, perforation; esophagitis

Megaesophagus

Progressive ethmoidal hematoma

Nasal or paranasal sinus neoplasia

Fistula (pharyngeal, esophageal, esophagobronchial, esophagotracheal, bronchobiliary)

Foreign body (nasal, pharyngeal, laryngeal, tracheal, bronchial)

Infarctive lobar pneumonia

Bronchopleural fistula

Pleural mesothelioma

Pneumothorax

Pulmonary tumor, primary or metastatic

Lymphosarcoma, lymphoma, leukemia

Pulmonary aspergillosis

Phycomycosis, pythiosis

Plant awn stomatitis

Anaphylaxis or acute drug reaction

Atrial fibrillation

Tetralogy of Fallot

Cor pulmonale

Endocarditis

Ruptured mitral chordae tendineae

Melioidosis, *Pseudomonas pseudomallei* (exotic)

Glanders (exotic)

African horse sickness (exotic)

5.1.3.1.4 TOXIC CAUSES

Crofton weed *(Eupatorium adenophorum)*

α-Naphthyl thiourea (ANTU)

Pentachlorophenol

Organophosphate

Carbamate

B, Bovine; *C*, caprine; *O*, ovine.

During forced expiration such as occurs with coughing, the increased pleural pressure is transmitted to the intrathoracic airways and alveoli. Intraalveolar pressure exceeds pleural pressure by an amount equal to the elastic recoil pressure of the lung.[4,11] A pressure gradient thus exists between the alveoli and atmospheric pressure at the nostrils and mouth. At a point in the airways known as the *equal pressure point* (EPP), the pressure in the airway lumen equals the pleural pressure because the elastic recoil pressure has been dissipated.[2–4,11] In the intrathoracic airways rostral to this point, the intraluminal pressure is lower than the pleural pressure; therefore a transmural pressure gradient exists, which tends to cause the airways to be dynamically compressed or collapsed.[2,4,11] The location of the EPP is determined by the elastic recoil pressure, and thus indirectly by lung volume, and by the frictional resistance to flow in the airways between the alveoli and the EPP.[4] At high lung volumes, elastic recoil pressure is high, resistance in peripheral airways is low, and the EPP is typically located in the larger intrathoracic airways, which have cartilaginous support for their walls, thereby preventing airway collapse.[4] As lung volume decreases, elastic recoil force decreases, airway resistance increases, and the EPP moves more peripherally, subjecting lower and less well-supported parts of the tracheobronchial tree to dynamic compression.[3,4,11] Dynamic compression reduces the cross-sectional area of intrathoracic airways and thus increases the velocity of airflow through the narrowed segment.[4] These spikes of accelerated airflow promote more effective shearing of mucus and debris from the airway wall and lumen during coughing.[11]

43

44

5.1.3.2 Box 5-2 Causes of Coughing in Ruminants

5.1.3.2.1 COMMON CAUSES

*Mannheimia hemolytica** or *Pasteurella multocida* pneumonia (includes shipping fever and enzootic calf pneumonia)

Haemophilus somnus pneumonia (B)

Lungworm infection, verminous pneumonia

Atypical interstitial pneumonia (B)

Chronic bacterial pneumonia with abscessation or consolidation (*Arcanobacterium [Actinomyces] pyogenes*[†] and other bacteria)

Infectious bovine rhinotracheitis (IBR; bovine herpesvirus type 1 [BHV-1]) (B, C)

Bovine respiratory syncytial virus (B)

Parainfluenza virus type 3

Mycoplasma species pneumonia

Caprine *Mycoplasma mycoides* subsp. *mycoides* infection (C)

Caprine arthritis-encephalomyelitis (CAE) pneumonia (C)

Necrotic laryngitis, calf diphtheria (B, O)

Abscess (oral, lingual, retropharyngeal, pharyngeal, laryngeal)

Trauma (pharyngeal, laryngeal, tracheal, bronchial, chest wall)

Esophageal obstruction, foreign body choke

Septicemia (neonates)

5.1.3.2.2

LESS COMMON CAUSES

Bovine rhinovirus (B)

Bovine adenovirus (B)

Bovine malignant catarrhal fever (B)

Bovine virus diarrhea (BVD-MD) (B)

Herpesvirus DN-599 (B)

Bovine herpesvirus type 4 (BHV-4) (B)

Bovine coronavirus (B)

Pulmonary adenomatosis (Jaagsiekte) (O)

Ovine adenovirus (O)

Caprine respiratory syncytial virus (C)

Ovine progressive pneumonia and arthritis, maedi (O)

Aspiration, foreign body pneumonia

Foreign body (pharyngeal, laryngeal, tracheal, bronchial, pulmonary)

Inhalation pneumonia (smoke, noxious gases, thermal injury)

Pulmonary embolus from posterior vena cava thrombosis (B)

Anaphylaxis or adverse drug reaction

Reaction to death of parasites after anthelmintic treatment (B)

Milk allergy in cows (B)

Farmer's lung disease (hypersensitivity to *Faenia rectivirgula* and other mold spores) (B)

Pleuritis, pleural effusion

Pneumothorax

Diffuse fibrosing alveolitis (B)

Left-sided heart failure (left atrioventricular [mitral] insufficiency, pericarditis, congenital cardiac defects, other causes)

High altitude disease (B)

Enzootic bovine leukosis (B)

Chlamydia psittaci pneumonia

5.1.3.2.3

UNCOMMON CAUSES

Diaphragmatic hernia

Pleural mesothelioma (B, C)

Sarcocystosis (B)

Sporadic bovine leukosis, thymic lymphosarcoma (B)

Tuberculosis

Tularemia (O)

Tracheal actinomycosis

Tracheal collapse, stricture, stenosis

Phycomycosis, pythiosis (B)

Pulmonary aspergillosis

Rhinosporidiosis

Zygomycosis, mucormycosis (B)

Pulmonary listeriosis (B)

Pneumocystis carinii pneumonia

Cor pulmonale (C)

Neoplasia (nasopharyngeal, oropharyngeal, pulmonary)

Postpartum hemolytic-uremic syndrome (B)

Esophageal rupture, laceration, ulceration, megaesophagus, hiatal hernia

Neoplasia, skeletal (B, O)

Buss disease, chlamydial sporadic bovine encephalomyelitis (B)

Winter dysentery (B)

Ascaris suum migration in calves (B)

Rinderpest (exotic)

Theileriosis, East Coast fever (exotic)

Melioidosis, *Pseudomonas pseudomallei* (exotic)

Contagious bovine pleuropneumonia (exotic) (B)

African bovine malignant catarrhal fever (exotic) (B)

Virulent sheep and goat pox (exotic) (O, C)

Peste des petits ruminants (exotic) (O, C)

Contagious caprine pleuropneumonia (exotic) (C)

Viral dermatitis of goats (exotic) (C)

Ibaraki disease (exotic) (B)

5.1.3.2.4

TOXIC CAUSES

Organophosphate, carbamate

Mercury (B)

Iodine (B, O)

Insect fogger (B)

Levamisole (O, C)

Nitrogen dioxide (B)

Hairy vetch *(Vicia villosa)* (B)

Sneezeweed (*Helenium* species)

Aflatoxicosis (C)

B, Bovine; *C*, caprine; *O*, ovine.

* Formerly named *Pasteurella hemolytica*.

† Formerly named *Actinomyces pyogenes*.

44

45

Dynamic compression also increases the resistance to airflow.[4] Once dynamic compression of peripheral (smaller) airways occurs, further increases in expiratory effort cause greater narrowing of the airway; thus the flow rate that can be generated at a given lung volume does not increase beyond a certain maximum point (maximum expiratory flow).[4] Maximum expiratory flow decreases progressively as the animal exhales because lung volume declines. Thus coughing beginning at high lung volumes achieves the highest airflows.[4] However, only the larger intrathoracic airways are compressed and subjected to these spikes of higher airflow velocity.[2,4,11] As lung volume falls or if cough is initiated at lower lung volumes, smaller airways are dynamically compressed

and cleared of mucus.[2,3,11] The effectiveness of coughing can thus be improved by repeating it several times in succession, either in a progression from high to low lung volume during the same breath or by inhaling between breaths.[4]

Because maximum airflows are lower in smaller airways, coughing is probably less effective in clearing material from the smaller airways than from the larger ones.[4] In the alveolar regions of the lung, gas flow is too slow for coughing to be an effective means of clearance.[11] Because only intrathoracic airways are dynamically compressed and subjected to these spikes of higher flow velocity during forced expiration, the extrathoracic trachea should be less effectively cleared by coughing.[4] However, horses and other animals with long necks do not seem to have great difficulty in clearing their airways, although they do lower their heads and straighten their airways during coughing to assist the clearance process.

In diseases such as RAO that cause narrowing of the airway lumen, the increased resistance to airflow, especially in peripheral airways, causes the EPP to move more peripherally toward the alveoli, resulting in a reduction in the maximum expiratory flow rate.[2,4] In this situation the effectiveness of coughing in clearing the airways is reduced. Thus administration of a bronchodilator may greatly improve the effectiveness of coughing in patients with RAO.[4]

5.1.3.3

COUGH STIMULI

Cough may be stimulated by bronchoconstriction, excessive mucous production, deposition of inhaled particles in the airways, release of inflammatory mediators (infectious diseases), exposure to hot or cold air, intramural or extramural pressure or tension on the airways (tumor, granuloma, abscess, or decreased pulmonary compliance caused by restrictive disease such as interstitial fibrosis or pleural effusion), sloughing of airway epithelial cells, and enhanced epithelial permeability (pulmonary edema).[12] Epithelial sloughing and enhanced epithelial permeability theoretically increase the accessibility of cough receptors to the mechanical or chemical agents that stimulate them. Loss of integrity of the epithelial lining of the respiratory tract is a common feature in many respiratory diseases associated with cough (infectious diseases); however, a cause-and-effect relationship between alterations in pulmonary epithelium and cough has not been established.[12] Diseases of the respiratory tract may alter the sensitivity of the cough reflex.[12] For example, viral infections may increase the responsiveness of cough receptors to stimuli.[7,12] Of the many causes of coughing in large animals, viral infections such as equine influenza and infectious bovine rhinotracheitis (IBR) are particularly important, because they cause outbreaks of respiratory disease that has acute onset of coughing as a prominent feature and that is frequently associated with persistence of coughing for prolonged periods after signs of acute disease have abated. These features of viral infections reflect the decreased effectiveness of mucociliary clearance resulting from virus-induced injury to ciliated epithelial cells, together with exposure and sensitization of irritant airway receptors, which lead to persistent bronchial hyperreactivity.[4,13] Affected individuals show bronchoconstriction and coughing in response to mildly irritating stimuli such as dust, stable pollutants, cold air, dry air, and exercise that would not normally cause coughing. Coughing subsides only when the airway epithelium has healed, which takes approximately 7 weeks.[4]

The role of mucus in coughing is not clear.[4] Fluid flushed over the tracheobronchial epithelium stimulates irritant receptors, particularly if the fluid is hypertonic or hypotonic.[9,10,14] Coughing is also stimulated by fluid that lacks permeant anions (i.e., anions that have a hydrated size and membrane-penetrating characteristics similar to the chloride anion).[15] Excessive accumulation of mucus in the airways may mechanically stimulate

irritant receptors and cause coughing.[4] However, mucus may have a protective effect by coating the epithelium with a layer that separates the receptors from the irritants.[4]

Coughing is a prominent feature of cardiac disease in many species, although cardiac diseases are not often encountered in large domestic animals. Failure of the left side of the heart as a result of congenital defects, valvular stenosis or incompetence, conduction disturbances, myocardial disorders, or restrictive pericardial disease causes an increase in pressure in the pulmonary venous return from the lung. This results in transudation of fluid from the pulmonary capillaries into the pulmonary parenchyma and airspaces (cardiogenic pulmonary edema) and causes swelling of the mucosal lining of small airways.[2] These changes stimulate cough receptors and initiate the cough reflex. Coughing that occurs secondary to cardiac disease is usually chronic, although acute-onset coughing may be observed with ruptured mitral chordae tendineae and bacterial endocarditis.[16]

5.1.4 Approach to Diagnosis of Coughing

5.1.4.1 HISTORY

The history should include questioning relative to the patient, the cough, the environment, and management. The *age* of the affected animal is important because many conditions have a marked age incidence. For example, *R. equi* pneumonia occurs primarily in foals younger than 6 months of age, equine herpesvirus type 4 predominantly affects weanling and yearling horses, atypical interstitial pneumonia (fog fever) affects predominantly pastured adult cattle, and RAO affects primarily mature stabled horses. The *use of the horse;* its state of fitness; the presence of vices such as crib biting; and any *history of contact with other horses* at shows, events, sales, racetracks, or breeding farms should be determined.

Recent stressors such as transportation, surgery, strenuous activity, or weaning should be determined, because these are known risk factors for conditions such as pneumonia and pleuropneumonia. The duration of ownership of the animal, its previous health, and the geographic location of origin, if it was recently purchased, may help identify regional diseases not normally seen in the area (e.g., systemic mycosis, lungworms, or silicosis in horses) or indicate the degree of stress likely to have been recently experienced. For recently purchased feedlot cattle and sheep, it should be determined if the animals were preconditioned before sale, their place of origin, the number of sale yards through which they have passed, and the duration of transportation.

When evaluating for potentially contagious diseases or those related to common environmental conditions, the vaccination status of the affected animal and herdmates and the presence of similar clinical signs in other in-contact animals sharing common facilities or common airspaces should be determined. In nursing animals the vaccination status of the dam is important. A history of other signs such as anorexia, nasal discharge, weight loss, exercise intolerance, stridor, lymphadenopathy, facial swelling, diarrhea, colic, and edema may provide important clues to the cause of the current problem. Weight loss occurs in many acute and chronic diseases, both infectious and noninfectious. Anorexia may indicate that the animal feels too systemically sick to eat, that it has a sore throat, or that it is devoting so much effort to breathing that it will not eat.

45 46

Environmental considerations such as the introduction of new animals into the environment or the return of animals from shows, sales, training centers, or breeding farms should increase the suspicion of infectious viral or bacterial diseases such as IBR in cattle or influenza in horses. For diseases such as *R. equi* pneumonia in foals, it is useful to know if similar cases have been seen on the premises in the past. The type of housing or pasturing facilities should be evaluated, particularly with regard to airspace, ventilation, sanitation, stocking

density, dust, shade, and shelter. Equine stabling facilities that have enclosed barns, particularly when the stalls face a central arena or are located under a hay storage loft, promote the spread of contagious agents and almost invariably increase the concentration of dust, mold spores, and noxious gases such as ammonia and tractor exhaust fumes in the environment. The type of feed and bedding, storage facilities, and feeding arrangements should be evaluated, especially in chronically coughing horses suspected of having allergic lung disease. Quantitative measures of ventilation and environmental quality can be made and can prove helpful in case management and in monitoring the effectiveness of measures to reduce environmental dust and other pollutants.[17] Similarly, the sampling of air in barns or paddocks using special devices that allow quantitation of bacterial pathogens such as *R. equi* may prove to be useful for assessing risk of infection.

A history of recent access to lush green pastures is frequently obtained in cattle with atypical interstitial pneumonia (fog fever). The quality of the feed should be evaluated visually and by smell, particularly with regard to the presence of mold spores. General management, pasture management, and parasite control measures should also be evaluated, especially if lungworm infection is suspected. Horses with lungworm infection almost invariably have a history of current or previous co-grazing with donkeys. The season and seasonal incidence of recurrence of the coughing can provide useful clues (e.g., marked seasonal worsening of signs in the late autumn when horses are stabled suggests chronic allergic respiratory disease). The history should also include the nature of previous treatments and the response.

Important historical features of the cough include the time and speed of onset; frequency; duration (chronic if longer than 1month); relation to feeding, housing, or weather; relation to exercise and timing during exercise; improvement, deterioration, or other change since onset; and the presence of and similarity to previous episodes of coughing or respiratory disease. Many coughs are exacerbated by exercise because exercise places greater stress on the respiratory tract. The resulting rapid airflow improves mobilization of secretions and irritates the airway directly. Coughs that occur during eating suggest specific or nonspecific sensitivity to molds, pollen, or other dusts in feed; inflammatory conditions of the larynx or pharyngeal region; laryngeal or pharyngeal problems, including complications of surgery, that interfere with swallowing or guarding of the lower airway; or esophageal obstruction (choke). The effort required to cough and associated pain may also give clues to the cause of the cough.

The character of the cough should be evaluated, because certain features of a cough tend to point toward its origin and possible causes but are by no means pathognomonic for either. Coughs originating in the upper airway are usually of acute onset, loud, harsh, coarse, dry, hacking, and nonproductive in character. Painful upper airway conditions such as acute pharyngitis, strangles, or necrotizing laryngitis can make the cough more muted. Lower airway coughs are usually soft, deep, and productive (mucus, pus) and tend to be more persistent than coughs originating in the upper airway. However, chest pain frequently attenuates coughing in horses with pleuropneumonia. In horses the fixed intranarial position of the larynx usually precludes expectoration of sputum into the mouth; thus the productive nature of the cough is difficult to assess. Excess mucus or exudate that is coughed up into the pharynx is usually swallowed; thus a cough can be productive without evidence of a nasal discharge. Swallowing efforts that follow a cough generally indicate that the cough is productive.

5.1.4.2

PHYSICAL EXAMINATION

The extent of the physical examination varies with the information already gained and the severity of the problem. It should include both distant and close evaluation of the patient and the environment. In addition to a detailed examination of the respiratory and cardiovascular systems, a general physical examination should be completed so that diseases in other systems can be detected and systemic manifestations of cardiopulmonary disease can be evaluated. The attitude of the animal, the respiratory rate and character, the presence of

excessive intercostal or abdominal respiratory effort or of a “heave line” or “barrel chest,” the presence and nature of respiratory distress or stridor at rest, and the presence and character of any nasal and ocular discharge should be noted before the animal is restrained. The following should then be determined: (1) rectal temperature, pulse rate, pulse rhythm and character, mucous membrane color, and capillary refill time; (2) symmetry of airflow from each nostril; (3) odor from the nostrils and mouth; (4) facial symmetry and swelling; (5) resonance or painful response on percussion of the maxillary and frontal sinuses; (6) enlargement of submandibular, parotid, retropharyngeal, and other regional lymph nodes; (7) enlargement of the parotid salivary glands or thyroid gland; (8) swelling, pain, or palpable abnormalities in the retropharyngeal region; (9) palpable swelling or flattening of the cervical trachea; and (10) masses at the thoracic inlet and palpable turbulence such as a tracheal rattle in the extrathoracic airway. The oral cavity should also be examined. If spontaneous coughing is not heard during the physical examination, a cough should be induced after auscultation of the airways by pinching the larynx or trachea, and it should be ascertained whether the induced cough sounds like the animal's spontaneous cough. Pinching of the trachea generally causes normal animals to cough once or twice, whereas it often induces paroxysmal coughing in animals with lower airway disease. The laryngeal or tracheal cough reflexes show increased sensitivity in most infective and inflammatory airway diseases.[16]

The larynx, trachea, lungs, and heart should be carefully *auscultated* on both sides of the chest in a quiet environment with the animal at rest and after the rate and depth of respiration have been increased by application of a rebreathing bag, by temporary occlusion of the nostrils, or by light exercise (see Cyanosis, p. 68). This permits detection of turbulent airflow, increased or decreased bronchovesicular sounds, wheezes, crackles, pleural friction rubs, or pleural fluid splashes, all of which indicate disease of the airways, pulmonary parenchyma, or pleura. Wheezes and crackles reflect airway narrowing and dynamic airway collapse, respectively, and are both evidence of small airway disease.[16] A small or medium-size plastic trash bag makes an adequate rebreathing bag; a plastic rectal sleeve is satisfactory for foals or calves if the opening is stretched so that it does not occlude the nostrils. The response to application of a rebreathing bag should also be noted. Most horses tolerate this procedure well and breathe more deeply, whereas animals with chest pain often do not. Normal horses do not cough when the bag is applied unless they have been eating recently, whereas horses with airway irritation caused by pneumonia or other conditions often cough paroxysmally in response to application of a rebreathing bag. The time taken to regain the normal respiratory rate and character after removal of the bag provides a reasonable crude indicator of ventilatory reserve. Normal animals recover quickly, within a few breaths, whereas respiration may be altered for several minutes in animals with significant lung disease.

46

47

The chest wall should be *palpated* to detect pleural friction rubs or lesions such as rib fractures, and the symmetry of chest expansion should be determined. Unilateral chest pain (pleurodynia) often reduces chest excursion on the affected side. Both sides of the chest should be *percussed* systematically to detect changes in resonance and chest pain. The caudoventral percussion border in the normal horse traces from the level of the tuber coxae at the seventeenth intercostal space (the horse normally has 18 pairs of ribs) to the level of the tuber ischii at the fifteenth intercostal space to the midthorax at the thirteenth intercostal space to the level of the point of shoulder at the eleventh intercostal space; it continues as a curving line to a point 1 to 3 inches above the olecranon. The normal caudoventral percussion boundary in cattle and small ruminants traces from the eleventh intercostal space at the level of the lateral edge of the epaxial musculature to the ninth rib at a level halfway between the costochondral junction and the lateral edge of the epaxial musculature to the fifth rib at the olecranon (cattle, goats, and sheep normally have 13 pairs of ribs). Percussion is an important diagnostic tool in all large animals, but it is most useful in foals, calves, and goats. The precise percussion boundaries, degree of resonance, and auscultation findings are influenced by age, size, body condition, fitness, and hair coat, as well as by disease processes; a gas-filled abdominal viscus can also confuse interpretation.

Hyporesonance (dullness) may indicate pulmonary consolidation, large mass lesions, cardiomegaly, pleural effusion, or other pleural disease. Free pleural fluid usually causes an abrupt change from normal resonance above a horizontal fluid line to hyporesonance below this line. Hyperinflation or pneumothorax may cause hyperresonance with or without expansion of the normal percussion boundaries. A painful response to percussion may indicate pleuritis or some other inflammatory process involving the parietal pleura.

In cattle the presence of thoracic or cranial abdominal pain should be ascertained by application of upward pressure to the xiphoid area with the knee or by application of downward pressure with both hands just caudal to the withers. Animals with cranial abdominal or thoracic pain resist these maneuvers and may make an audible or auscultable grunting noise. Signs such as jugular distention or pulsation (or both) and peripheral edema, which may indicate heart failure, should be noted; and the heart should be auscultated to detect murmurs, dysrhythmias, muffling of heart sounds, or other abnormalities that would indicate the need for further cardiovascular diagnostic procedures.

5.1.4.3

COMPLETE BLOOD COUNT

A complete blood count, including fibrinogen concentration, usually reveals nonspecific findings but may be useful in the evaluation of cases in which primary or secondary inflammatory conditions are suspected and in conditions such as pulmonary thromboembolism secondary to caudal vena cava thrombosis (CVCT) in cattle and guttural pouch mycosis in horses in which blood-loss anemia is likely to be a complicating problem. Acute viral infections often induce a transient anemia and leukopenia, predominantly lymphopenia, followed by a monocytosis during recovery. Neutrophilia and hyperfibrinogenemia are features of many inflammatory conditions but are usually most marked when bacterial infection is involved. Some parasitic diseases (e.g., lungworm infection in cattle) may induce eosinophilia, as may allergic conditions, but eosinophilia is not a common feature of either lungworm infection or allergic RAO in the horse.

5.1.4.4

NASAL OR NASOPHARYNGEAL SWABBING

Nasopharyngeal swabbing and direct cytologic examination and culture are indicated for confirmation of viral or bacterial infections that involve the upper airway. Because a large number of bacteria normally inhabit the nasopharynx, only the presence of *Streptococcus equi* or some other pathogen not considered part of the resident flora can be considered significant. When clinical signs suggest a viral respiratory infection, especially when an outbreak of coughing occurs in several animals, *molecular detection by polymerase chain reaction (PCR), antigen detection by antigen-capture enzyme-linked immunosorbent assay (ELISA)*, or *virus isolation* from nasal or nasopharyngeal swabs, tracheal wash, and/or buffy coat (ethylenediaminetetraacetic acid [EDTA] blood) samples collected during the acute phase of the disease and *viral serologic tests* on acute and convalescent serum samples are indicated.[18] Under these circumstances, sampling as many of the most severely affected, often younger, animals as early as possible in the disease course maximizes the chances of establishing an etiologic diagnosis. Large absorbent Dacron or rayon swabs[*] should be used for nasopharyngeal swabbing. The swab should be placed in viral transport medium for dispatch to the diagnostic laboratory if virus isolation is desired, and the laboratory should be notified in advance that samples will be submitted. Antigen-capture ELISA[†] and PCR tests are now available for testing of nasal or nasopharyngeal swabs and other samples to confirm a diagnosis of viral infection.[18] These rapid-screening tests are sensitive, less cumbersome to perform than virus isolation, do not require such stringent conditions for handling and transporting samples, and provide results sufficiently quickly that specific control measures can be implemented. However, they do not yield an isolate that can be used to monitor genetic and antigenic evolution of the viral agent. Serologic testing often provides only retrospective information, but it can prove very helpful

in the formulation of future control measures, including vaccination. The larger the number of animals tested, the more informative are the results of serologic testing in a herd or flock. Serologic testing is also indicated when pneumonia caused by *Coccidioides immitis* or other fungal agents is suspected.

5.1.4.5

ENDOSCOPIC EXAMINATION

Endoscopic examination of the nasal passages, conchae (turbinates), pharynx, larynx, and trachea allows the presence, nature, and source of exudates and the presence of anatomic or functional abnormalities or mass lesions to be noted. Endoscopic examination of the upper airway of the horse to evaluate for partial airway obstruction is best performed without the use of sedatives or tranquilizers if possible because these alter the tone and function of the muscles supporting laryngeal and pharyngeal anatomy and function and confuse interpretation of endoscopic findings. In the horse the interior of the guttural pouches may be examined by advancing the endoscope through the pharyngeal openings of each guttural pouch using a guide wire such as a closed biopsy instrument passed through the biopsy channel of the endoscope and into the pouch. Most coughing horses have lower airway disease, which may be reflected in accumulation of endoscopically visible exudate in the horizontal trachea, particularly after exercise. Lungworm larvae may be grossly visible in the trachea of horses with lungworm infection. Deeper bronchoscopic examination is necessary to determine whether exudate is a reflection of diffuse airway disease or whether it arises from a specific area of the lung, such as would occur with a pulmonary abscess or a foreign body lodged in a bronchus. Sedation may or may not be needed to permit endoscopic examination of the extrathoracic airways in the standing horse; however, sedation with xylazine, detomidine, or romifidine supplemented with butorphanol is recommended to facilitate bronchoscopy and to dampen the cough reflex, as is spraying of the carina and bronchial branches with 2% lidocaine via the biopsy channel of the endoscope to reduce coughing during the procedure. Tracheobronchial aspiration and bronchoalveolar lavage (BAL) can be performed by introduction of appropriate catheters via the biopsy channel of the endoscope.

47

48

5.1.4.6

TRACHEAL ASPIRATION

Tracheal aspiration with cytologic studies and quantitative or semiquantitative aerobic and anaerobic culture of collected samples is indicated in the evaluation of patients suspected of having disease of the lungs or pleura, particularly if an infectious cause is likely. Tracheal wash samples collected using the percutaneous transtracheal technique are preferred for bacterial culture because they are not contaminated by oropharyngeal organisms.[19,20] Collection of samples by introduction of a sterile catheter through the biopsy channel of a presterilized endoscope inserted within a sterile sheath, or by introduction of a double-sheathed catheter via the biopsy channel, is acceptable and less subject to complications than is the transtracheal technique, but samples obtained transendoscopically may be contaminated with *Pseudomonas* species and anaerobic bacteria despite use of a guarded technique.[20] If tracheal aspiration is to be performed percutaneously, the procedure should precede endoscopic examination of the lower airways to avoid contamination. Culture may fail to reveal the primary bacterial pathogen, especially in animals that have been treated with antibiotics. The diagnostic value of tracheal wash samples can be improved by discontinuing antibiotic therapy for at least 24 hours before collecting samples, rapidly processing samples, using antibiotic removal devices and selective culture media and, if necessary, repeating sampling. Culture results should be evaluated in relation to the clinical signs, clinical experience (especially on the farm of origin of the patient), results of cytologic evaluation, and

response to treatment. The trachea is not a sterile environment; therefore, culture of small numbers of bacteria without cytologic evidence of infection is of questionable significance.

5.1.4.7

BRONCHOALVEOLAR LAVAGE

Samples collected by BAL are less useful than those collected by tracheal aspiration for evaluating infectious lower airway diseases and focal pulmonary conditions because the technique samples secretions from only a limited area of the caudodorsal lung on one side and is subject to contamination during collection. However, BAL yields better samples for cytologic assessment and is therefore preferred for evaluation of patients with generalized, noninfectious lower airway diseases such as RAO or silicosis.[18] BAL samples can be collected under endoscopic guidance by means of catheters introduced through the biopsy channel of a suitable endoscope (less than 9mm in diameter and longer than 180cm) or by using commercially available BAL tubes. The advantage of collection via endoscopy is that specific areas of the lung can be sampled, although gaining access to the cranial lung lobes is difficult with any method. Differential cell counts in BAL fluid of normal horses vary depending on age, environment, activity, and other factors. In young horses (<6 years of age), the distribution of macrophages, lymphocytes, neutrophils, mast cells, and eosinophils is on average 65%, 30%, 3%, 0.5%, and 0%, respectively.[21] In horses >6 years of age, the neutrophil population may reach 15% in normal horses, with a corresponding decrease in the proportion of lymphocytes and macrophages.[21]

Neutrophils are usually the predominant cell type in BAL fluid or tracheal washes of horses with RAO and in animals with bacterial infections. The neutrophils usually show degenerative changes when significant bacterial infection is present. Large numbers of eosinophils are a feature of parasitic infections such as lungworms, some allergic conditions, and infiltrative eosinophilic interstitial pneumonia. The presence of hemosiderin-laden macrophages is an indication of recent pulmonary hemorrhage, and finding refractile intracytoplasmic granules in macrophages or giant cells should raise the suspicion of silicosis, especially in animals showing radiographic evidence of marked pulmonary interstitial disease. Noting the presence, number, location (intracellular or extracellular), and Gram stain characteristics of bacteria permits a reasoned selection of antibiotic treatment while awaiting the results of culture and susceptibility tests.

5.1.4.8

ULTRASOUND EXAMINATION

Ultrasound examination is useful for examining externally visible lesions such as possible retropharyngeal abscesses that may be impinging on the airway and causing coughing. Ultrasound examination of the chest is indicated to determine the presence and extent of pleural effusion, pleural roughening, pleural fibrin deposits, gas echoes in pleural fluid, pleural adhesions, and pulmonary lesions such as consolidation, atelectasis, or abscessation in animals with lesions in contact with the pleural surface or in animals in which sufficient pleural fluid has accumulated to allow evaluation of the underlying lung. The tissue-to-air interface at the visceral surface of the normal lung appears as a thin, smooth, bright echogenic line on ultrasound because it reflects the ultrasound beam, precluding visualization of deeper structures. Penetration of the ultrasound beam beyond the surface of the lung occurs only in the presence of lung pathology that extends to the visceral pleural surface of the lung in the area being scanned.

5.1.4.9

BLOOD GAS ANALYSIS

Blood gas analysis on arterial blood to determine oxygen (O_2) and carbon dioxide (CO_2) tensions is indicated in the evaluation and monitoring of patients in which a history or clinical signs of coughing are accompanied by signs of respiratory distress or cyanosis (see Respiratory Distress, p. 60, and Cyanosis, p. 68).

5.1.4.10

THORACOCENTESIS

Thoracocentesis with culture and cytologic examination of collected samples is indicated in animals with clinical or ultrasonographic evidence of effusive pleural disease. Normal pleural fluid is odorless, pale yellow to straw colored, and transparent and has a total nucleated cell count of <10,000/μL cells, most of which are mononuclear cells (macrophages and mesothelial cells), and a protein concentration of <2.5g/dL.[18] Determination of the pH and concentrations of glucose, lactate, and lactate dehydrogenase (LDH) in pleural fluid collected into a heparinized tube or syringe helps differentiate septic from nonseptic effusions while awaiting culture results.[22] Septic effusions are typically acidic (pH <7.2), have a low glucose concentration (<40mg/dL), a high LDH concentration (>1000IU/L), and a lactate concentration higher than that present in venous blood.[22–24] The best site for collecting pleural fluid can be confirmed by ultrasonography after auscultation and percussion of the chest. The sixth or seventh intercostal spaces at the level of the costochondral junction are commonly used sites in horses and cattle. The thorax should be penetrated in the part of the intercostal space immediately adjacent to the cranial border of the rib to avoid the intercostal vessels and nerves.

48 49

5.1.4.11

PLEUROSCOPY

Pleuroscopy is a more invasive procedure with limited indications that include investigation of chronic pleural diseases such as abscesses, pleural adhesions, and possible primary or metastatic pulmonary or pleural neoplasia such as lymphosarcoma, gastric squamous cell carcinoma, or mesothelioma.

5.1.4.12

FECAL EXAMINATION

Fecal examination using the Baermann technique to detect lungworm larvae is indicated in ruminants suspected of having a lungworm infection. Because lungworm infections in the horse rarely become patent, larvae are not usually demonstrable by fecal examination. Pulmonary signs related to *Parascaris equorum* infection in foals occur during the prepatent (migratory) period; therefore the fecal flotation test for ascarid eggs often yields a negative result despite significant parasitic infection.

5.1.4.13

RADIOGRAPHIC EXAMINATION

Radiography of the chest is indicated in patients suspected of having lower airway disease to determine the presence, severity, and pattern of disease changes involving the lungs, pleura, and mediastinum. Four overlapping lateral projections usually are required to evaluate the whole lung field in an adult horse. Because ventrodorsal projections are possible only in young foals, lateral projections from each side may be necessary to lateralize lesions within the chest. Radiographs of the lungs are particularly useful for determining the prognosis and for monitoring the response to therapy of pulmonary diseases such as bacterial pneumonia and lung abscesses. The cardiac silhouette and the pattern and caliber of the aorta, vena cava, pulmonary artery,

pulmonary veins, and other vessels should be evaluated for evidence of cardiac failure and pulmonary vascular disease. Radiographs of the pharynx, retropharyngeal area (including guttural pouches in the horse), larynx, and proximal trachea are indicated in some cases to confirm problems not definitively diagnosed by clinical examination and endoscopy.

5.1.4.14

NUCLEAR SCINTIGRAPHY

Nuclear scintigraphy using aerosolized technetium-99m (^{99m}Tc)–labeled diethylenetriaminepentaacetic acid (DPTA) and intravenously injected ^{99m}Tc-labeled microaggregated albumin particles has been used to determine patterns of pulmonary ventilation, perfusion, and ventilation/perfusion ratios.[19,25] This technique requires special equipment and personnel but provides an objective assessment of pulmonary function and gas exchange capability.[25]

5.1.4.15

BIOPSY

Biopsy, with histologic evaluation of samples, is indicated to diagnose certain mass lesions such as neoplasms, cysts, polyps, fungal granulomas, or foreign body granulomas in or surrounding the airway. Masses in the airway can be biopsied through the biopsy channel of an endoscope, but these samples inevitably are small. Biopsies can also be collected at the time of exploratory or corrective surgery from lesions in the upper airway. Lung biopsies can be collected blindly, using Tru-Cut, Biopty, or similar instruments, preferably from the peripheral areas of the lung to reduce the likelihood of serious hemorrhage (see Chapter 31). Focal lesions should be visualized ultrasonographically or radiographically before or during the biopsy procedure. Lung biopsy is most useful for diagnosing diffuse nonseptic conditions such as pneumoconiosis. The inherent risks associated with the procedure indicate that percutaneous lung biopsy should be reserved for circumstances in which the animal is not showing signs of marked respiratory distress, uncontrollable coughing, or bleeding disorders and a high likelihood exists that the procedure will yield significant diagnostic information. Open lung biopsy is rarely indicated.

5.1.4.16

IMMUNOGLOBULIN DETERMINATIONS

Quantitative immunoglobulin determinations and possibly other *immune function tests* may be indicated in animals, especially young ones, with chronic or recurrent respiratory tract infections or other indications of immune compromise.

5.1.4.17

ALLERGEN TESTING

Intradermal allergen testing (IDT), a radioallergosorbent test (RAST), ELISA tests for immunoglobulin E (IgE) on serum, and *inhaled challenge* have been advocated for the evaluation of horses suspected of having allergic respiratory disease based on exacerbation of signs in certain environments or with certain feeding practices. Whereas there are anecdotal reports that horses with RAO have been hyposensitized successfully using allergens selected on the basis of these allergen tests, we are unaware of documentation in well-controlled studies. In addition, a recent study showed that compared with normal nonatopic horses, RAO-affected horses did not have a significantly greater number of positive reactions in intradermal skin tests (IDT) against any allergen group (molds, grasses, weeds, trees, and insects), leading the authors to conclude that reactions to individual allergens in IDTs should not be used to determine that horses have clinically relevant hypersensitivity.[26] Many normal horses show sensitivity to individual mold spores and other allergens, and

there is poor correlation between the dermal and pulmonary reactivities to mold antigens.[13] Furthermore, when compared with the results of IDT, RAST and ELISA serum allergy tests have been shown to have low sensitivity in detecting allergen sensitivity.[27] Whereas the use of recombinant allergens rather than crude mold extracts in ELISA tests substantially improves sensitivity in detecting levels of allergen-specific IgE,[28] and significantly more RAO-affected horses than normal horses have high allergen-specific IgE levels, the degree of overlap of results precludes use for diagnostic purposes.[29] The crude trial-and-error approach of adding or removing potential allergens from the environment is sometimes very helpful diagnostically and therapeutically in RAO cases in which an allergic cause is suspected. Feeding of pellets instead of hay and using shredded paper, peat moss, or wood shavings instead of straw bedding are common examples of this approach (see the section on RAO in Chapter 31).

5.1.4.18

PULMONARY FUNCTION TESTING

With the exception of measurement of pleural pressure using an esophageal balloon catheter attached to a pneumotachograph, pulmonary function testing and evaluation of airway dynamics during exercise have until recently been largely research techniques that were not readily applicable to clinical patients. Recent development of the minimally invasive techniques of oscillometry (forced oscillatory mechanics [FOM]), forced expiratory maneuvers, and flowmetrics now permits physiologic assessment of lung function in clinical patients.[30,31] When coupled with histamine provocation tests to assess airway reactivity and bronchodilator response tests, pulmonary function tests can provide a considerable amount of information to guide therapy and prognosis. Indications for pulmonary function testing might include evaluating horses with a history of poor performance or exercise intolerance but no other detectable abnormalities; assessing the degree of functional impairment in horses with known evidence of respiratory disease; assessing the efficacy of therapeutic regimens; determining if a horse has recovered from a diagnosed respiratory disorder and can be returned to training; and ruling out functional pulmonary abnormalities in horses with upper airway conditions.

5.1.4.19

BRONCHODILATOR RESPONSE TESTING

Bronchodilator response testing involves determining the response of measured pulmonary functions and pleural pressures to rapidly acting bronchodilator drugs such as albuterol (450 to 900mcg) or ipratropium bromide, administered by aerosol, or atropine administered parenterally.[30] Results are often helpful in determining the pathogenesis of RAO and the likely response to bronchodilator therapy. In the field setting, useful information can be gained by assessing the response of respiratory rate, respiratory character, and lung sounds to intravenous (IV) administration of a low dose of atropine (5 to 7mg/450-kg horse). This test can be made more objective by measuring pleural pressures using a Ventigraph recorder* attached to an esophageal catheter or flowmetric techniques.[13,30,32,33]

* Boehringer Ingelheim, Vet Medica, Inc., St Joseph, Mo.

5.1.4.20

DIFFERENTIAL DIAGNOSIS OF COUGHING

The differential diagnosis of coughing can be enhanced by arbitrarily categorizing it on the basis of *duration of signs* into acute or chronic (more than 1month) and by the *presence or absence of fever*.[34] It should be kept in mind that some acute coughs become chronic and that, conversely, conditions that cause chronic coughing may be seen early in the disease course. Conditions typically associated with *acute coughing* include viral, bacterial, and parasitic infections of the upper and lower respiratory tract; acute allergic reactions or acute toxic injury to

the lung such as in atypical interstitial pneumonia (fog fever) of cattle; foreign bodies; choke; injuries to the larynx, trachea, or chest; pharyngeal or laryngeal dysfunction secondary to neurologic disorders or surgery; aspiration of food material or foreign bodies; smoke inhalation; and compressive upper airway lesions such as retropharyngeal abscesses or necrotic laryngitis. In most instances, outbreaks of sudden-onset coughing in groups of animals are the result of viral infection involving the upper and lower respiratory tract.[8,16]

Conditions typically associated with *chronic coughing* include chronic bacterial pneumonia; pulmonary abscess; chronic pleuritis; chronic allergic pulmonary diseases such as RAO in horses and farmer's lung disease in cattle; postviral bronchial hyperreactivity, chronic viral respiratory disease such as ovine progressive pneumonia and caprine arthritis-encephalomyelitis pneumonia; irritant airway disease caused by environmental irritants such as dust; lungworm infections, particularly in horses and small ruminants; functional or anatomic problems in the pharynx or larynx that interfere with guarding of the airway, including postsurgical problems; heart failure resulting in pulmonary edema; tumors or polyps in the upper airway or lung; mycotic infections of the upper airway, lung, or pleura; chronic guttural pouch infections in horses; tracheal collapse, especially in ponies; chronic interstitial disease such as pneumoconiosis caused by inhalation of particulate material; and so-called “nuisance coughs.” Nuisance coughs are common in horses, especially at the beginning of exercise, which emphasizes the fact that coughing is a normal airway protective mechanism and not always evidence of disease. Nuisance coughs tend to bother the owner more than the horse and can result from habit; vices such as crib biting, wind sucking, or greedy eating; and environmental factors such as dust, ammonia, and cold air. Some of these nuisance coughs are correctable by modifying the stabling or work environment.

Cough with fever usually indicates a primary infectious cause or a secondary infection superimposed on a noninfectious cause.[34] Fever is a typical but not an invariable feature of aspiration pneumonia, bacterial pneumonia, pulmonary abscess, viral respiratory tract infection, strangles, fungal pneumonia, pleuropneumonia (bacterial, viral, or mycoplasmal), acute bronchointerstitial pneumonia, and thoracic neoplasia.[34]

Cough without fever is typically found in RAO, abnormalities of the larynx or pharynx, parasitic pneumonia, exercise-induced pulmonary hemorrhage (EIPH), tracheobronchial foreign body, tracheal collapse, and airway-oriented neoplasia (e.g., bronchial carcinoma).[34] Horses with chronic interstitial pneumonia such as silicosis or granulomatous pneumonia are usually afebrile but may have mild to moderate fever.[1]

5.2 NASAL DISCHARGE

5.2.1 Definition

Nasal discharge, which is any nongaseous material that exits the respiratory tract through the external nares, is described according to its *physical characteristics* (serous, mucoid, purulent, hemorrhagic [sanguineous], or a combination of these types or feed material); *acuteness of onset* (sudden or insidious); *origin* (unilateral or bilateral); *volume* (profuse or scant); and *association with activity* (spontaneous or intermittent).[35–37]

5.2.2 Pathophysiology

5.2.2.1 NORMAL NASAL SECRETIONS

The ciliated, pseudostratified columnar epithelium lining the respiratory tract from the nasal passages to the level of the respiratory bronchioles contains serous, mucous, and mixed tubuloalveolar glands in its lamina

propria.[35] Goblet cells are present in large numbers throughout the nasal cavity and are present in the airway mucosa to the level of secondary and tertiary bronchi.[35] The secretions of these glands and goblet cells and the fluid transudated from serum together serve to warm and humidify inspired air, trap particulate matter, protect the respiratory epithelium from desiccation and infection, and provide the serous-mucous bilayer necessary for effective ciliary function.[38,39] The tracheobronchial fluid that constitutes the mucous blanket in the lower parts of the respiratory tract contains exfoliated epithelial cells, alveolar macrophages, and other mononuclear cells, glycoproteins, bacteriostatic proteins (primarily lysozyme), lactoferrin, secretory IgA, IgG, IgM, and serum proteins (primarily albumin).[38,39] The cilia lining the pseudostratified columnar epithelium beat in coordinated waves to carry mucus, trapped particles, and cells from the lower respiratory tract to the nasopharynx. Material cleared from the tracheobronchial tree is normally swallowed on reaching the pharynx but may appear at the external nares as nasal discharge.[39]

Serous nasal secretions in normal animals are responsible for the moist appearance of the ventral portion of the external nares. In cattle normal nasal secretions are more voluminous and more mucoid compared with other large animal species. Healthy cattle keep their external nares clean through licking. Cattle that are systemically ill or otherwise debilitated often neglect to do this, and as a result mucoid secretions accumulate and crust around the external nares. On the other hand, a buildup of nasal discharge in cattle with respiratory disease can be removed by frequent nose licking, masking the presence of disease.

50

51

Lacrimal secretions also drain into the nasal passages through the nasolacrimal ducts and may appear at the external nares as a thin, watery, clear, nonviscous discharge, particularly in animals with conjunctival irritation or ocular inflammatory diseases that stimulate excessive lacrimation.[36]

5.2.2.2

ABNORMAL NASAL SECRETIONS

Inflammatory conditions involving the nasal cavity stimulate increased production of glandular secretions.[39] These secretions initially are serous but later become mucoid and purulent as secondary bacterial invasion induces an influx of neutrophils.[35] Serous nasal discharge generally indicates disease conditions affecting the nasal passages or upper respiratory tract.

Inflammation, irritation, and other pathologic states affecting the trachea and bronchi increase the production of mucous and serous secretions in the tracheobronchial tree[39] (Boxes 5-3 and 5-4). Initially the accompanying nasal discharge is mucoid (clear, colorless, thin, and elastic in consistency), but with chronicity and secondary bacterial invasion, neutrophils and other inflammatory cells accumulate in the tracheobronchial secretions and the nasal discharge becomes purulent, progressing from cloudy to opaque and then to viscous with a whitish cream color (Boxes 5-5 and 5-6).

Conditions such as chronic bronchitis and RAO cause goblet cell hyperplasia and increased mucous production, which may be reflected as a discharge at the external nares, depending on the efficiency with which the animal swallows these secretions. In some cases nasal discharge is evident only early in the morning or after a period of recumbency because in these situations secretions accumulate in the trachea and pharynx, drain into the nasal passages, and exit from the nares.

5.2.2.2.1

Box 5-3 Causes of Serous and Mucoid Nasal Discharge in Horses

5.2.2.2.1.1

COMMON CAUSES

Influenza

Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)

Rhinovirus

Other viruses (e.g., adenovirus, reovirus, EHV-2)

Pharyngitis, chronic pharyngeal lymphoid hyperplasia

Nasal or paranasal sinus infection, cysts, polyps, tumors

Early bacterial pneumonia or pleuritis

Early strangles (*Streptococcus equi* infection)

Guttural pouch infection, mycosis

Overflow of nasolacrimal ducts

Recurrent airway obstruction (RAO or COPD)

5.2.2.2.1.2

LESS COMMON CAUSES

Equine viral arteritis

Burn (thermal, chemical)

Anaphylaxis or acute drug reaction

Aspiration or foreign body pneumonia, smoke inhalation

Foreign body (nasal, pharyngeal, guttural pouch, tracheal, or bronchial)

Summer pasture—associated obstructive airway disease (SPOAD)

5.2.2.2.1.3

UNCOMMON CAUSES

Nasal fungal infection (rhinophycomycosis), aspergillosis

Nasal amyloidosis

Coccidioidomycosis

Restrictive pulmonary disease, pneumoconiosis

Trauma to the skull or upper airway

Tuberculosis

Tularemia

Guttural pouch neoplasia

Chlamydia psittaci pneumonia

Nocardiosis

Cryptococcosis

Fungal granuloma, maduromycosis, rhinosporidiosis, mycetoma, pythiosis

Lungworm infection *(Dictyocaulus arnfieldi)*

Ascarid migration

Cyst (pharyngeal, subepiglottal)

Progressive ethmoidal hematoma

Lymphosarcoma, lymphoma, leukemia

Halicephalobus (Micronema) deletrix granuloma

Pulmonary edema

Pulmonary aspergillosis

Stachybotryotoxicosis

Trichloroethylene-extracted feed toxicity

Pentachlorophenol toxicity

Organophosphate, carbamate toxicity

Ammonia toxicity

St George disease (*Pimelea* species poisoning) (exotic)

Trypanosoma evansi, surra (exotic)

Trypanosoma equinum, mal de caderas (exotic)

Trypanosoma hippicum, murrina de caderas (exotic)

Besnoitiosis, globidiosis (exotic)

African horse sickness (exotic)

Getahvirus (exotic)

Glanders (exotic)

Louping ill (exotic)

Hemorrhagic (sanguinous) nasal discharge, or epistaxis, occurs secondary to trauma, coagulopathies, and erosive or invasive conditions that insult the richly vascular nasal mucosa or secondary to conditions that invade regional blood vessels such as occurs when the internal carotid artery is eroded by a mycotic plaque in

horses with guttural pouch mycosis. Pulmonary disorders such as infarctive pneumonia in horses and pulmonary thromboembolism secondary to posterior vena cava thrombosis in cattle may also induce epistaxis (see Epistaxis, p. 56).[35–37]

Foul odor (ozena) accompanying nasal discharge suggests an anaerobic infection, a necrotizing condition (e.g., fungal infection, neoplasia, turbinate necrosis, or necrotizing pneumonia), foreign body, or communication between the oral and nasal cavities (e.g., maxillary sinusitis secondary to a patent infundibulum in the horse).[37]

Food or water may drain from the external nares when there is communication between the oral and nasal cavities (e.g., cleft palate); in association with swallowing disorders (e.g., pharyngeal paresis secondary to botulism, cranial nerve damage secondary to guttural pouch mycosis in the horse); or in cases of obstructive dysphagia (e.g., severe pharyngitis, guttural pouch enlargement in horses, retropharyngeal abscesses, esophageal obstruction, obstructions of the gastrointestinal tract that lead to regurgitation of food from the stomach).[35–37] The respiratory position of the epiglottis dorsal to the soft palate in the horse means that except in cases of dorsal displacement of the soft palate (laryngopalatal dislocation), food regurgitated from the digestive tract enters the nasopharynx and appears at the external nares rather than at the mouth (see Regurgitation and Vomiting, Chapter 7).

5.2.2.2.4.4 TOXIC AND EXOTIC CAUSES

See Box 5-4, p. 52

B, Bovine; *C*, caprine; *O*, ovine.

Chronic nasal discharges often cause scalding in the area ventral to the external nares.[36] Mucoid and purulent nasal discharges tend to dry and crust as an admixture with environmental dust and dirt around the external nares. In all large animal species but particularly in sheep and goats, tenacious exudates may obstruct the nasal passages and induce a snuffling noise. Horses with profuse nasal discharge often rub the nose on the dorsum of the front fetlock and cannon regions. During the physical examination these areas should be inspected for mucoid exudate, dried crusts, or swarms of flies.

5.2.2.3 ACUTENESS OF ONSET

Sudden-onset nasal discharge usually is associated with acute infection, trauma, or esophageal obstruction, whereas nasal discharge of insidious onset generally accompanies chronic infection, progressive neurologic disease that causes dysphagia, or neoplasia.[40]

5.2.2.4 ORIGIN OF NASAL SECRETIONS

Unilateral nasal discharge generally originates from structures located rostral to the caudal end of the nasal septum. Bilateral nasal discharge results from disease processes affecting structures caudal to the caudal end of the nasal septum or from conditions involving the nasal passages or paranasal sinuses bilaterally.[36,37] A discharge that appears from one nostril on some days and from the opposite nostril on others generally indicates a lesion or disease process caudal to the nasal septum.[37] The paired guttural pouches of the horse drain separately through ostia located dorsolaterally in the wall of the nasopharynx. Exudate draining from the guttural pouches may appear unilaterally at the ipsilateral nostril if the volume of drainage is small, but moderate to profuse guttural pouch drainage appears as a bilateral nasal discharge.[37]

5.2.2.5

VOLUME OF NASAL SECRETIONS

The volume of nasal discharge frequently increases when the head is lowered, regardless of the source of the discharge, because of pooling of exudate in the trachea, pharynx, or nasal passages. However, the appearance of profuse, unilateral, purulent nasal discharge when the head is lowered generally indicates sinus empyema, and profuse bilateral nasal discharge under these circumstances suggests guttural pouch empyema.[20] This is attributed to accumulation of large volumes of exudate in the sinus cavities or guttural pouches when the head is elevated and to the fact that the ostia through which these structures drain are not located on the most dependent aspect of these cavities; thus significant drainage can occur only when the head is lowered. Nasal discharge observed only after exercise suggests an origin in the lower respiratory tract.[41]

5.2.3

Approach to Diagnosis of Nasal Discharge

Because many conditions, particularly those involving the lower respiratory tract, are associated with both nasal discharge and cough, the diagnostic approach used for large animal patients presented for evaluation of nasal discharge is similar to that used for large animals presented for evaluation of cough (see Cough, p. 42). Only those components of the history and diagnostic evaluation that differ substantially from those used in patients with cough are described in depth in this section.

5.2.3.1

HISTORY

The patient history should include information about the rapidity of onset and duration of nasal discharge; whether the discharge is consistently unilateral, consistently bilateral, or intermittently bilateral; and the volume, color, consistency, and odor of the discharge.

The association of discharge with certain activities such as initiation of exercise, when the animal is first disturbed in the morning, or when it is eating with its head lowered can provide useful clues to the origin or cause. It should be determined if the animal is showing other signs of respiratory disease (e.g., cough, respiratory distress, or exercise intolerance), dental disease (e.g., quidding or slow eating), or systemic disease (e.g., weight loss, depression, anorexia, fever, or lymphadenopathy).

It should also be determined if in-contact animals have exhibited nasal discharge or other signs of respiratory disease. The vaccination status of affected and in-contact animals should be ascertained. Recent stressors such as transportation, surgery, or weaning should be noted, and a history of contact with other animals at sales, shows, or other events should be established. Environmental quality and the overall management of the affected animal and the herd should be assessed (see Cough, p. 42). Progression or improvement in the signs, attempted therapy, and response to current or previous treatments should also be ascertained.

5.2.3.2

PHYSICAL EXAMINATION

Physical examination of an animal showing nasal discharge should include inspection from a distance and close examination using *auscultation, palpation*, and *percussion* techniques (see Physical Examination, p. 46, and Cough, p. 42). The character and volume of the nasal discharge should be noted. Particular attention should be paid to whether:

- The nasal discharge is unilateral or bilateral

- The airflow from both nostrils is symmetric
- Odor emanates from the oral or nasal cavity
- Facial asymmetry is present
- Hyporesonance (dullness) or a painful response is elicited on percussion of the maxillary and frontal sinuses
- Enlargement of submandibular, parotid, retropharyngeal, or other regional lymph nodes is present
- Palpable turbulence, such as a tracheal rattle, is present

The depth and symmetry of chest expansion should be assessed, and the rostral end of both nasal passages should be illuminated with a penlight and examined carefully.

The roots of the third through the sixth maxillary cheek teeth (108 to 111 and 208 to 211) in the horse are contained within the maxillary sinus; therefore infection of these teeth frequently leads to sinus empyema with drainage from the nasomaxillary opening into the middle nasal meatus and ultimately to a unilateral nasal discharge. Disease involving the paranasal sinuses should be considered in horses with unilateral nasal discharge, particularly when ozena is present. Under these circumstances a thorough *oral examination*, which should include probing of the occlusal surfaces of the maxillary cheek teeth with a fine dental pick, is indicated. Particular attention should be paid to detecting erosive periodontal disease, fractured maxillary cheek teeth, open pulp chambers, and patent infundibula. In cattle the oral examination should include palpation of the base of the tongue, the oropharynx, and, if possible, the larynx to detect mass lesions or swelling of the tongue.

Further diagnostic evaluation of nasal discharge may include a complete blood count with determination of the fibrinogen concentration, a serum biochemistry profile, endoscopy of the upper and lower airways and the esophagus, nasal or nasopharyngeal swabbing for molecular diagnostic testing or virus isolation, virus serologic testing, tracheal aspiration, BAL, ultrasonography, thoracocentesis, radiography, blood gas analysis, nuclear scintigraphy, fecal examination, pulmonary function testing, and lung biopsy. For further information on diagnostic procedures not discussed in the following sections, see Cough, p. 42.

54

55

5.2.3.3

ENDOSCOPIC EXAMINATION

Endoscopic examination of the upper and lower airways is a useful ancillary diagnostic procedure in all animals with nasal discharge. The nasal passages; the conchae (turbinates), including the ethmoidal conchae; the nasal septum; and the pharynx, larynx, and trachea should be examined through both nostrils. The presence, nature, and origin of exudates and the presence of anatomic or functional abnormalities or mass lesions should be noted. Although it is not possible to introduce standard, 8- to 12-mm—diameter endoscopes into the paranasal sinuses via the nasal passages, drainage from the sinuses may be detected by examining the middle meatus.[37] Examination of the middle meatus may also reveal turbinate necrosis or mass lesions (e.g., tumors, fungal granulomas, nasal foreign bodies). Lesions such as progressive hematomas (expanding mass lesions of variable size on the ethmoid turbinates) can be visualized by advancing the endoscope slightly, after deflecting its tip dorsally through the common meatus, from a position in the caudal part of the ventral meatus just rostral to the choana. In the horse the pharyngeal openings of the guttural pouches, which are located dorsolaterally on the wall of the pharynx, should be inspected for drainage. The interior of both guttural pouches can be examined for exudate, blood, mycotic plaques, and other proliferative lesions by advancing the endoscope

through the pharyngeal openings of each guttural pouch. This procedure is facilitated by first introducing a biopsy instrument or similar guide wire into the guttural pouch via the biopsy channel of the endoscope.

Bronchoscopic examination may prove useful for identifying the bronchus of origin of pulmonary exudates and for facilitating appropriate BAL. In horses with intermittent bilateral nasal discharge, it may be helpful to repeat the endoscopic examination after exercise, which often mobilizes secretions from the lower respiratory tract and causes them to pool in the horizontal trachea. Endoscopic examination of the esophagus is indicated in patients with a history of dysphagia or return of ingesta through the nose (Boxes 5-7 and 5-8).

5.2.3.4

RADIOGRAPHY

Radiography with lateral, dorsoventral, and oblique radiographic projections of the nasal passages, paranasal sinuses, pharynx, retropharyngeal area (including guttural pouches in the horse), larynx, and proximal trachea is indicated to confirm problems identified by clinical examination and endoscopy and to identify conditions not recognized by other diagnostic techniques. The demonstration of increases in tissue density, fluid lines, bony lysis or proliferation, distortion of normal architecture, or changes around tooth roots assists in the diagnosis and localization of disorders of the nasal passages, conchae, and paranasal sinuses. Space-occupying lesions in the oropharynx, nasopharynx, or larynx may also be demonstrated by radiographic examination of these areas. The presence of fluid lines, soft-tissue densities, or thickening of the floor of the guttural pouches helps differentiate guttural pouch diseases (e.g., empyema) from other space-occupying lesions (e.g., abscesses) in the retropharyngeal region. Contrast radiographic studies such as barium swallows are indicated to evaluate aspiration during swallowing in horses suspected of having pharyngeal paresis. Carotid angiography under general anesthesia has been used to demonstrate aneurysms in the internal carotid artery of horses with guttural pouch mycosis.[42] Thoracic radiographs are indicated in patients suspected of having pulmonary, mediastinal, or pleural disease to determine the presence, pattern, and severity of radiographic changes.

5.2.3.4.1

Box 5-7 Causes of Ingesta in Nasal Discharge in Horses

5.2.3.4.1.1

COMMON CAUSES

Esophageal obstruction, choke

Cleft palate, palatal hypoplasia (neonate)

Pharyngitis

Strangles (*Streptococcus equi* infection)

Dorsal displacement of the soft palate

Guttural pouch infection, mycosis, neoplasia

Glossopharyngeal nerve damage

Botulism, shaker foal

Retropharyngeal abscess

5.2.3.4.1.2

LESS COMMON CAUSES

Complications of laryngeal surgery

Laryngeal web defect

Epiglottal entrapment, subepiglottal abscess or cyst

Tetanus

Fistula (pharyngeal, esophageal, esophagobronchial, esophagotracheal)

Esophageal stricture, ectasia, diverticulum, megaesophagus, ulcer, rupture

Gastric, duodenal ulceration (foals)

Gastric dilation, rupture

Proximal enteritis, jejunitis

Small intestinal obstruction

Rabies

Other neurologic deficits affecting swallowing

5.2.3.4.1.3

UNCOMMON CAUSES

Persistent right aortic arch, vascular ring anomaly

Gastric tumor

Gastric stenosis

Rostral displacement of the palatopharyngeal arch

Hypoplasia of the soft palate

White muscle disease, nutritional myodegeneration

Rectus capitis ventralis muscle rupture

Lymphosarcoma, lymphoma, leukemia

Oleander poisoning

White snakeroot (tremetol) poisoning

Lead toxicity

Grass sickness (exotic)

5.2.3.5

COMPUTED TOMOGRAPHY SCANNING

When a definitive diagnosis is not achieved using plain radiographs, computed tomography (CT) scanning with the horse positioned in dorsal recumbency under general anesthesia has proven valuable for more accurately defining the location, nature, and extent of lesions involving the nasal passages, paranasal sinuses, and cheek teeth.[43,44] Intracarotid or IV injection of contrast material further enhances the diagnostic utility of CT for evaluation of mass lesions.

5.2.3.6

ULTRASOUND EXAMINATION

Ultrasound examination of externally visible lesions such as possible retropharyngeal abscesses or distended guttural pouches assists in characterization of lesions and collection of samples by aspiration or biopsy. Thoracic ultrasound is indicated when lower airway, pleural, or cardiac disease is the suspected cause of nasal discharge.

5.2.3.7

PERCUTANEOUS ASPIRATION

Percutaneous aspiration, performed either blindly or with the assistance of ultrasound, followed by cytology and culture of aspirated material, is useful in the evaluation of masses such as submandibular or retropharyngeal abscesses that are also causing a nasal discharge.

5.2.3.7.1

Geigeria species poisoning

Sneezeweed (*Helenium* species) poisoning

Rubberweed (*Hymenoxys* species) poisoning

B, Bovine; *C*, caprine; *O*, ovine.

5.2.3.8

CENTESIS

Centesis of affected paranasal sinuses helps localize the source of exudates and provides samples for cytologic examination and culture in patients with chronic unilateral nasal discharge in which sinus percussion or radiographic examination (or both) suggests the presence of a sinus lesion. In the normal horse the rostral and caudal maxillary sinuses are separated by a thin osseous septum. This septum is often eroded in horses with septic sinusitis; therefore the caudal maxillary sinus is typically entered first. If no exudate can be aspirated, either directly or after lavaging the sinus, and if increased purulent drainage from the ipsilateral nostril is not accomplished during lavage, centesis of the rostral maxillary sinus is performed and the procedure repeated. If the aspirated material is not malodorous and if there is no evidence of dental disease, there is a reasonable likelihood that primary (nondental) sinusitis is present. In the horse the rostral maxillary sinus can be entered at a site 2.5cm dorsal and 2 to 3cm caudal to the rostral end of the facial crest. The caudal maxillary sinus is entered at a point 2.5cm dorsal to the facial crest and 2cm rostral to the medial canthus of the eye. After shaving and surgical preparation of the skin and subcutaneous placement of a small volume of local anesthetic, a stab incision is created through the skin and extended down to the periosteum. A small hole is then drilled through the bone with a Steinmann pin in a hand-held chuck or a 14-gauge needle. A 14-gauge cannula is introduced into the sinus and, if necessary, a No. 5 French catheter can be inserted through the cannula to facilitate sample collection and lavage (see Diseases of the Paranasal Sinuses, Chapter 31).

5.2.3.9

CATHETERIZATION

Catheterization of the guttural pouches via the pharyngeal orifice, either blindly or under endoscopic guidance, followed by aspiration or lavage, culture, and cytologic examination of aspirated contents is helpful in the evaluation of horses with chronic purulent nasal discharge in which guttural pouch empyema is suspected or has been confirmed by radiographic or endoscopic examination. In horses with large accumulations of fluid exudate, voluminous drainage of pus both through and around the catheter may occur when the pouch is first

catheterized. In horses with chronic guttural pouch infection accompanied by tenacious or inspissated exudate, lavage with 250 to 400ml of sterile saline or Ringer's solution facilitates sample collection.

5.3 EPISTAXIS AND HEMOPTYSIS

5.3.1 Definition

Epistaxis is defined as the presence of blood at the external nares[45]; the amount of blood at the nostrils can range from small flecks incorporated in serous nasal discharge to large volumes flowing freely from both nostrils. Hemoptysis is the coughing up of blood.[46]

5.3.2 Pathophysiology

Blood at the external nares originates from one or more of the following structures: nasal cavity, paranasal sinuses, guttural pouch (auditory tube diverticulum), oral cavity, pharynx, larynx, trachea, or lungs.[45] These respiratory structures may be affected by a primary disease process or may be one of many mucosal surfaces involved in a bleeding diathesis (Boxes 5-9 and 5-10). The actual disease condition, the affected structure, and the large animal species involved determines whether epistaxis is profuse or scant, unilateral or bilateral, induced by exercise, accompanied by hemoptysis, and/or associated with concurrent abnormal nasal discharge.

5.3.2.1 NASAL CAVITY OR PARANASAL SINUS PATHOLOGIC CONDITIONS

Epistaxis associated with diseased respiratory tract structures rostral to the caudal border of the nasal septum (e.g., nasal cavity, paranasal sinuses) usually is unilateral and appears spontaneously (i.e., occurs without exertion or lowering of the head). However, with profuse hemorrhage from these sites, blood may drain caudally, accumulate in the pharynx, and exit from both nostrils.

Nasal cavity structures are highly vascular and prone to injury. Bleeding can be caused by foreign bodies, fungal granulomas, or neoplasms that invade the nasal cavity; epistaxis associated with these lesions is commonly unilateral, scant, and evident only intermittently. Trauma induced by passage of a nasogastric tube or endoscope is the most common cause of profuse hemorrhage of nasal origin in horses.[45] Erosive diseases that affect the paranasal sinuses of horses (e.g., progressive ethmoidal hematoma)[45] or sheep (endemic nasal adenocarcinoma)[47] commonly cause a unilateral, serosanguineous nasal discharge preceded or accompanied by mucopurulent discharge. In the case of sinusitis the exudate often is malodorous, particularly when the process occurs secondary to dental disease. Epistaxis resulting from fractures of the nasal bones or skull can be scant or profuse, depending on the extent of the fracture.

5.3.2.2 PATHOLOGIC CONDITIONS OF THE GUTTURAL POUCHES OF THE HORSE

Spontaneous epistaxis that occurs at rest in a mature horse warrants consideration of the guttural pouch as the source of hemorrhage.[48] In the case of guttural pouch mycosis, epistaxis is typically caused by fungal erosion of the internal carotid artery in the roof of the medial compartment of the guttural pouch.[48–50] The horse initially experiences several episodes of minor hemorrhage characterized by a small amount of fresh blood at the external nares; this may be preceded by a unilateral catarrhal nasal discharge and followed by a seromucous nasal discharge. Ultimately, massive arterial bleeding associated with erosion of the internal carotid artery

manifests as large volumes of blood gushing from both nostrils.[49] Epistaxis caused by bleeding from the guttural pouch is typically most pronounced on the ipsilateral side, but nasal bleeding is usually bilateral in this condition, especially if hemorrhage is profuse, because the nasopharynx drains into both nasal passages.[50]

5.3.2.2.1

Box 5-9 Causes of Epistaxis in Horses

5.3.2.2.1.1

COMMON CAUSES

- Exercise-induced pulmonary hemorrhage (EIPH)
- Guttural pouch mycosis
- Progressive ethmoidal hematoma
- Nasal trauma
- Pharyngeal or retropharyngeal trauma or abscess
- Nasal polyps
- Tumors (nose, paranasal sinuses)
- Foreign body (nasal, pharyngeal, laryngeal, tracheal, bronchial)
- Purpura hemorrhagica

5.3.2.2.1.2

LESS COMMON CAUSES

Stachybotryotoxicosis (*Stachybotrys* species)

Mycotoxicosis

B, Bovine; *C*, caprine; *O*, ovine.

5.3.2.3

PULMONARY PATHOLOGIC CONDITIONS

In horses, pulmonary hemorrhage manifests as bilateral epistaxis, most often during or immediately after strenuous exercise.[45] However, in many cases of pulmonary hemorrhage, epistaxis may not be observed because blood originating from the lungs is swallowed when it reaches the pharynx. Hemoptysis, the hallmark of pulmonary hemorrhage in cattle, is rarely observed in horses because the laryngopalatal articulation of the horse fixes the larynx in an intranarial position and generally prevents blood flow from the nasopharynx to the oropharynx and mouth. In contrast to humans and other animal species, where foaming of blood exiting the nares suggests pulmonary hemorrhage, foaming of the blood is rarely encountered in horses with pulmonary hemorrhage because the horizontal position of the major bronchi allows blood to pool and flow freely without having to be coughed up.

EIPH, a syndrome experienced by 40% to 75% of thoroughbred racehorses and by horses of other breeds engaged in strenuous activity, is characterized by hemorrhage into the tracheobronchial tree during competitive exercise.[45,51,52] Although pulmonary hemorrhage can be identified by endoscopic examination of the trachea immediately after exercise in these horses, EIPH manifests as frank epistaxis at the external nares in only a small percentage of cases.[51] Bleeding at the nares may range from a slight orange-tinged serous nasal discharge to a constant trickle of fresh blood that persists for several hours after exercise.[45,52] The exact source of hemorrhage in horses with EIPH has not been identified, but it is known that affected horses have proliferation of the bronchial arterial blood supply to the lungs.[53] Fatal massive epistaxis, an infrequent sequela to exercise, has been attributed to tearing of the lung in association with pleural adhesions or focal shear stress.[54] Other less common causes of postexercise pulmonary hemorrhage in horses include pulmonary abscesses or pleuropneumonia with pulmonary infarction; in these cases the odor of the breath may be fetid, and hemorrhage may occur spontaneously (without exercise), which aids in the differentiation of these conditions from EIPH.[45,55]

CVCT (also known as *pulmonary embolic aneurysm* or *pulmonary thromboembolism*) is the disease most likely to be associated with epistaxis and hemoptysis in cattle (Box 5-11).[56] This sporadic, fatal condition of feedlot cattle is the result of a four-step sequence of events that culminates with the rupture of a pulmonary artery aneurysm into a bronchus. Initially, affected cattle exhibit tachypnea, lethargy, painful cough, melena, and anemia. Terminally the disease is characterized by discharge of bright, foamy red blood from the nose and mouth, severe respiratory distress, and widespread pulmonary crackles.[56]

5.3.2.3.1

Box 5-11 Causes of Hemoptysis in Ruminants

Caudal vena cava thrombosis (CVCT)

Aspiration pneumonia

Pharyngeal or retropharyngeal abscess or trauma

Thoracic trauma (fractured ribs or sternum)

Foreign body (nasal, oropharyngeal, tracheal, bronchial)

Pulmonary aspergillosis

Pulmonary edema present in the terminal stages of left-sided heart failure may also be responsible for bilateral serosanguineous discharge at the external nares of large animals.[45]

5.3.2.4 PATHOLOGIC CONDITIONS OF THE ORAL CAVITY, PHARYNX, OR LARYNX

Less often, epistaxis can result from bleeding from lesions in the oral cavity, pharynx, or larynx. Examples include oral cavity erosions associated with infectious diseases (e.g., mucosal form of bovine virus diarrhea infection in cattle, or bluetongue in sheep); erosions associated with epiglottic entrapment in horses; foreign bodies wedged in the mouth or pharynx of large animals; and pharyngeal or retropharyngeal trauma caused by a “balling gun.”

5.3.2.5 BLEEDING DIATHESIS

Several inherited and acquired coagulation disorders of large animals manifest as epistaxis.[57] Inherited clotting factor deficiencies (usually deficiencies of factors VIII, IX, or XI) or acquired factor deficiencies (those caused by warfarin, sweet clover toxicosis, or advanced liver disease) cause bleeding from large vessels. In addition to epistaxis, subcutaneous hematomas, hemarthrosis, melena, and hematuria, prolonged bleeding from sites of injury may be observed. With conditions causing vasculitis (e.g., equine purpura hemorrhagica, equine viral arteritis), small vessel bleeding occurs. Vasculitis is characterized by mucous membrane petechiae and ecchymoses and demarcated areas of skin edema. Nasal mucous membrane petechiae associated with vasculitis may manifest as epistaxis. Similarly, thrombocytopenia (e.g., immune-mediated thrombocytopenia in horses, bracken fern toxicosis in cattle) is characterized by mucous membrane petechiae and occasionally epistaxis. In rare cases disseminated intravascular coagulation (DIC) in large animals manifests as a consumptive coagulopathy with bleeding from mucous membranes and blood at the external nares.

5.3.3 Approach to Diagnosis of Epistaxis and Hemoptysis

5.3.3.1 HISTORY

History taking should closely follow that described for animals with nasal discharge and should include duration of ownership, time of first appearance of blood at the nares, number of times the animal has bled, volume and color of blood, presence of blood at one or both nostrils, association of epistaxis with exercise,

swallowing motions or cough after exercise, concurrent hemoptysis, other signs of respiratory tract disease (e.g., stridor, cough, nasal discharge, respiratory distress), evidence of involvement of cranial nerves (e.g., feed particles at the nares, drooping of the lip or ear), possibility of recent trauma (e.g., nasogastric intubation or head injury), and exposure to toxic plants (e.g., bracken fern or sweet clover).

5.3.3.2

PHYSICAL EXAMINATION

A complete physical examination should be performed to detect abnormalities indicative of systemic disease or disease affecting other body systems. This examination should include assessment of the attitude of the animal; determination of rectal temperature, pulse rate, and respiratory rate and character; evaluation of mucous membranes for color and petechiae; inspection of the animal to detect hematomas or prolonged bleeding from sites of injury or venipuncture; and neurologic examination to detect neurologic dysfunction (e.g., dysphagia, Horner's syndrome, facial paralysis, head tilt, or nystagmus), which may accompany guttural pouch mycosis. 58 59

5.3.3.3

EVALUATION OF THE HEAD AND RESPIRATORY SYSTEM

A complete evaluation of the head and respiratory system should also be carried out. The nasal bones and flat bones overlying the maxillary and frontal sinuses should be examined for asymmetry or deformation; the eyes should be evaluated for exophthalmos or epiphora; the nasal mucosae should be inspected with a light source to demonstrate erosive, ulcerative, or mass lesions; and the sinuses should be percussed to detect altered resonance or pain. On continuing the examination, the following should be evaluated: symmetry and amount of airflow through the nostrils and the effect of occluding each nostril independently; odor at the nose or mouth; presence of stridor; and the effect of applying pressure to the larynx or trachea. The oral cavity should be carefully inspected in animals in which epistaxis is accompanied by a necrotic breath odor. Special attention should be paid to the maxillary cheek teeth of horses and the base of the tongue and the oropharynx of all large animals. Structures in the external pharyngeal region (mandibular lymph nodes, Viborg's triangle, retropharyngeal lymph nodes, parotid salivary gland) should be observed and palpated for swelling, heat, or pain, and the trachea should be observed and palpated where exposed to detect any abnormalities. The larynx, trachea, and lungs should be carefully auscultated at rest and after application of a rebreathing bag for abnormally loud breath sounds, crackles, or wheezes, which may implicate pulmonary disease as the cause of epistaxis. Careful cardiac auscultation should be carried out to detect murmurs or dysrhythmias, which may be associated with left-sided heart failure and pulmonary edema. The chest wall should be palpated to detect rib fractures or pleural friction rubs, and the thorax should be percussed bilaterally to demonstrate large mass lesions, pleural effusion, or pleurodynia.

5.3.3.4

COMPLETE BLOOD COUNT

A complete blood count and assessment of fibrinogen concentration can be useful in the evaluation of animals with primary or secondary inflammatory conditions or those that have developed blood loss anemia as a sequela to epistaxis (e.g., horses with guttural pouch mycosis or cattle with pulmonary thromboembolism secondary to CVCT). The degree of anemia may give an indication of the severity and chronicity of the bleeding or, in cases of bracken fern poisoning, of the degree of bone marrow suppression.

5.3.3.5

CLOTTING PROFILE

A clotting profile should be performed (platelet count, prothrombin time [PT], activated partial thromboplastin time [APTT], concentration of fibrin degradation products [FDPs], and plasma antithrombin III) if mucous

membrane petechiae or a tendency to bleed was noted on the general physical examination or if the history suggests exposure to sweet clover, warfarin, or bracken fern.

5.3.3.6

BIOCHEMISTRY PROFILE

A biochemistry profile should be performed to detect disease processes in organ systems other than the lungs (e.g., increased liver enzyme activity in cattle with hemoptysis secondary to CVCT or animals with liver failure causing secondary clotting factor deficiency).

5.3.3.7

OCCULT BLOOD

Feces should be tested for occult blood. Positive results may suggest swallowing of blood originating from the lungs or pharynx or gastrointestinal bleeding.

5.3.3.8

ENDOSCOPIC EVALUATION

Endoscopic evaluation using a fiberoptic or video endoscope is a useful diagnostic aid in cases of epistaxis. The nasal passages, nasomaxillary aperture in the middle meatus, turbinates (conchae), nasal septum, pharynx, guttural pouches, larynx, and tracheobronchial tree should be systematically evaluated through both nostrils at rest and after exercise if indicated to determine the presence, nature, and source of blood and the anatomic or mass lesion responsible for the bleeding. Care should be taken when endoscopy is performed in horses with guttural pouch mycosis, because dislodging a clot of blood in the affected guttural pouch may result in fatal hemorrhage.[58] Similarly, the stress of endoscopy may prove fatal to cattle with pulmonary thromboembolism secondary to CVCT. If EIPH is suspected, endoscopy should be performed 30 to 120 minutes after strenuous exercise to allow time for the mucociliary escalator to transport blood to where it can be visualized[51]; this blood may persist from 6 hours to 4 days after exercise, depending on the severity of pulmonary hemorrhage. It is important to remember that EIPH may not be repeatable. In one study only 33% of thoroughbred racehorses tested positive for EIPH on all subsequent endoscopic examinations after breezing.[59] Biopsy (with histologic evaluation and possibly culture of samples) is indicated when granulomas, polyps, erosions, or mass lesions are visualized through the endoscope.

5.3.3.9

TRACHEAL ASPIRATION, BRONCHOALVEOLAR LAVAGE, AND THORACOCENTESIS

Percutaneous transtracheal aspiration or endoscopic tracheal aspiration, BAL, or thoracocentesis with cytologic studies and culture of collected samples is indicated when pulmonary or pleural diseases are thought to be responsible for hemorrhage into the respiratory tract. BAL is a technique best suited to evaluation of diffuse lung disease; BAL fluid analysis can yield a normal result in horses with focal lung disease (e.g., pulmonary abscess, pneumonia, or pleuropneumonia) because lavage fluid is instilled into a limited region of the lung.[60] Quantitative culture techniques should be used for samples obtained via BAL because contamination by nasopharyngeal organisms can occur.[61] Although there is a poor correlation between cytologic findings in tracheal wash fluid and histopathologic changes in the lungs of individual horses, increased cell counts with degenerative neutrophils and large numbers of intracellular and extracellular bacteria suggest a diagnosis of bronchopneumonia.[62] Percutaneously obtained tracheal wash samples are usually not contaminated by oropharyngeal organisms and can be submitted for culture[61]; transendoscopically obtained samples may be

contaminated with *Pseudomonas* species and anaerobic bacteria despite the use of guarded tracheal swabs.[63] The presence of hemosiderophages in tracheobronchial aspirates or BAL fluid is generally considered indicative of previous pulmonary hemorrhage[51]; however, mucopolysaccharides engulfed by alveolar macrophages can bind plasma iron in the absence of pulmonary hemorrhage to form an iron pigment resembling hemosiderin.[64]

5.3.3.10

RADIOGRAPHIC EXAMINATION

Radiographic examination of the nasal passages, paranasal sinuses, pharynx, retropharyngeal region (including the guttural pouches), larynx, and trachea is indicated if the source of nasal bleeding cannot be definitively diagnosed through physical examination and endoscopy. The nasal passages, turbinates, and paranasal sinuses should be evaluated for fluid lines, cystic structures, bony lysis or proliferation, distortion of normal architecture, or changes in the tooth roots. Space-occupying lesions in the pharynx and larynx may also be demonstrated by radiographic examination. Demonstration of a fluid-air interface in the guttural pouch may indicate guttural pouch hemorrhage or guttural pouch empyema.[45] New bone formation and sclerosis around the *temporohyoid articulation* may accompany mycotic infections of the guttural pouch.[45] CT examination may be indicated if the lesion in the head or neck causing hemorrhage cannot be defined adequately with plain radiographs. Thoracic radiographs using four overlapping lateral views in adult horses and cattle and lateral and ventrodorsal views in immature animals and small ruminants aid in identification and definition of diseases affecting the lungs, pleurae, and mediastinum.[61]

59

60

5.3.3.11

ULTRASOUND EXAMINATION

Ultrasound examination is used as an adjunct to thoracic radiology in animals suspected of having pleural effusion[61]; this procedure allows the examiner to determine the extent of the effusion and the presence of fibrin deposits or pleural adhesions. Pulmonary consolidation, atelectasis, infarction, and abscessation can also be demonstrated with this technique if these lesions are contiguous with the pleural surface.[61] Ultrasound examination of externally visible swellings such as enlarged retropharyngeal lymph nodes or distended guttural pouches may provide additional diagnostic information and may assist with appropriate placement of needles or biopsy instruments for sample collection.

5.3.3.12

PARACENTESIS

Paracentesis of the maxillary sinus[61] can be performed if percussion and inspection indicate that a lesion in the maxillary sinus may be the cause of epistaxis. Using sedation and analgesia, a small hole is trephined into the maxillary sinus with a Steinmann pin or 14-gauge needle; sinus contents can then be aspirated and submitted for cytologic and bacteriologic examination (see Nasal Discharge, p. 50).

5.3.3.13

PLEUROSCOPIC EXAMINATION

Pleuroscopic examination[65] can be performed in a standing, sedated patient by using a sterile rigid or fiberoptic endoscope. This procedure is indicated for patients in which large intrathoracic masses and adhesions have been demonstrated by thoracic radiology and ultrasonography. Pleuroscopy allows direct visualization of affected structures and provides an opportunity to biopsy masses or aspirate fluid. Pleuroscopy is a procedure

fraught with complications (e.g., pneumothorax, lung lacerations, infection) and should be reserved for cases in which less invasive procedures have failed to adequately diagnose the condition.[61]

In some teaching and research institutions *ventilation/perfusion ratios* can be measured in horses using nuclear scintigraphic techniques. A study of horses with EIPH demonstrated both ventilation and perfusion deficits in the dorsocaudal lung field that corresponded to the area in which EIPH lesions were detected at postmortem examination.[66]

5.4 TACHYPNEA

5.4.1 Definition

Tachypnea is the term used to describe an increase in the respiratory rate; the term *hyperpnea* is used when both the rate and depth of respiration have increased.

The respiratory rate, which is assessed by counting rib or nostril movements or by thoracic or tracheal auscultation, is best determined before the patient is disturbed or restrained. Under average conditions of temperature and humidity, acceptable ranges for the respiratory rate in normal adult animals are as follows: cattle, 10 to 30 breaths/min; horses, 8 to 15 breaths/min; sheep and pigs, 10 to 20 breaths/min; and goats, 25 to 35 breaths/min. Resting respiratory rates in young animals are higher than those in adults. A neonatal foal has a resting respiratory rate of 60 to 80 breaths/min during the first 30 minutes of life, a rate that later falls to 20 to 40 breaths/min. A young calf has a respiratory rate of 20 to 50 breaths/min by 30 minutes of age.

5.4.2 Pathophysiology

Respiratory rate, depth, and rhythmicity are regulated by respiratory centers in the brainstem. Central chemoreceptors responding to increased levels of CO_2 (decreased cerebrospinal fluid pH) and peripheral chemoreceptors (carotid and aortic bodies) responding to hypoxemia (Pa_{O_2} below 60mm Hg), increases in Pa_{CO_2}, and decreases in pH initiate increases in the respiratory rate. Mechanoreceptors in the lungs and joints also influence ventilation. Lung inflation stimulates stretch receptors in the airways, which decreases the inspiratory effort, whereas mechanoreceptors in the joints are thought to be partly responsible for the increases in ventilation that occur during exercise. Pulmonary chemoreceptors that influence the respiratory cycle include irritant receptors in the airways, which are stimulated by dust and histamine, and J receptors, which apparently detect levels of interstitial fluid and are thought to be responsible for the respiratory pattern observed in animals with pulmonary edema.

Tachypnea is classified as physiologic when it occurs in the absence of underlying disease and as pathologic when it is a manifestation of respiratory distress. Physiologic tachypnea is associated with pain, exertion, heat, fever, anxiety, and other stresses (Boxes 5-12 and 5-13). Factors predisposing to pathologic tachypnea are the same as those that cause respiratory distress: inadequate oxygenation of the blood (i.e., a need for additional oxygen); compensation for metabolic acidosis; excessive environmental heat; disorders that damage the central nervous system respiratory centers in the medulla (e.g., head trauma, inflammation, mass lesions) if they disrupt the control of breathing; disorders that cause dysfunction of motor nerves and/or weakness of respiratory muscles (e.g., botulism, myasthenia gravis, or diaphragmatic paralysis); and painful conditions involving the respiratory sensory nerves, muscles, pleurae, and ribs (e.g., chest trauma, pleural infection, or neoplasia)[67] (see Respiratory Distress, below).

5.4.3 Approach to Diagnosis of Tachypnea

Because tachypnea is a manifestation of respiratory distress, the approach used for evaluating patients with tachypnea is the same as that used for evaluation of respiratory distress (see below).

5.5 RESPIRATORY DISTRESS (DYSPNEA)

5.5.1 Definition

Respiratory distress indicates an inappropriate degree of effort to breathe based on an assessment of respiratory rate, rhythm, and character.[68,69]

Respiratory distress is a clinical sign that implies labored breathing, whereas dyspnea is a symptom that describes the subjective feeling of difficult, uncomfortable, or unpleasant breathing (shortness of breath) in human patients.[68–70] As such the term *dyspnea* is not strictly applicable to animal patients, although it is widely used by veterinarians to describe respiratory distress.

Manifestations of respiratory distress include elevated respiratory rate (see Tachypnea, at left), extended head and neck position, mouth breathing (ruminants), nostril flaring (horses, sheep, and goats), abnormal respiratory noise (stridor or stertor), exercise intolerance, exaggerated intercostal or abdominal effort (or both), a double expiratory lift and a “heave line” (expiratory respiratory distress), abducted elbows, stridor, anxious expression, and inactivity. Animals in severe respiratory distress may show cyanosis (see p. 68) and (especially those with severe RAO) may exert so much effort to breathe that the whole body rocks, the anus pumps in and out, and the animal does not move or eat because this diverts its energies from respiration.[69]

60

63

5.5.1.1 Box 5-12 Causes of Tachypnea in Horses*

5.5.1.1.1 COMMON RESPIRATORY CAUSES

Bacterial pneumonia

Pleuropneumonia, pleuritis

Pulmonary abscessation

Recurrent airway obstruction (RAO or COPD)

Viral pneumonia (equine influenza, adenovirus, equine viral arteritis, others)

Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)

Aspiration pneumonia

Prematurity, dysmaturity, or immaturity (foals)

5.5.1.1.2 COMMON NONRESPIRATORY CAUSES

Hyperthermia (fever, postexhaustion syndrome, heat stroke, anhidrosis, other)

Pain (abdominal crisis, laminitis, exertional myopathy, other)

Acidosis (acute enterocolitis, urinary bladder rupture, renal tubular acidosis, other)

Anaphylaxis

Blood transfusion reaction

Shock (hypovolemic, cardiac, septic)

Anemia (neonatal isoerythrolysis, blood loss, hemolytic anemia, iron deficiency, bone marrow suppression, ruptured middle uterine artery, other)

Cardiac disease (ruptured mitral chordae tendineae, ventricular septal defect, endocarditis, other)

Gastric dilation

5.5.1.1.3 LESS COMMON RESPIRATORY CAUSES

Smoke inhalation pneumonia

Parasitic pneumonia *(Dictyocaulus arnfieldi)*

Stenotic nares, choanal atresia

Nasal septum abnormalities

Neoplasia (nose, paranasal sinuses)

Fungal granuloma

Nasopharyngeal cicatrix

Paranasal sinus infection

Dorsal displacement of the soft palate

Pharyngeal or retropharyngeal abscess or trauma

Epiglottic entrapment

Chondroma of arytenoid cartilage

Guttural pouch empyema

Tracheal stenosis, collapse, stricture

Foreign body (nasal, nasopharyngeal, laryngeal, tracheal, bronchial)

Diaphragmatic hernia

Pneumothorax

Thoracic trauma

5.5.1.1.4 LESS COMMON NONRESPIRATORY CAUSES

Anaphylaxis

Air embolism

Intracarotid injections

Fluid therapy complications

Tetanus *(Clostridium tetani)*

Malignant edema *(Clostridium septicum)*

Malignant hyperthermia

Meningoencephalitis

Anemia (piroplasmosis, iron deficiency, hemolytic blood loss, other)

Cardiovascular anomalies (tetralogy of Fallot, tricuspid insufficiency, atrial septal defect, hypoplastic left heart, transposition of great vessels, persistent right aortic arch, patent ductus arteriosus)

Cor pulmonale

Pericarditis

Atrial fibrillation

Ventricular tachycardia, fibrillation, flutter

5.5.1.1.5

UNCOMMON RESPIRATORY CAUSES

Pulmonary lobar hypertrophy

Branchial or thyroglossal duct cyst

Tracheal rupture

Fracture of laryngeal cartilage

Fracture of hyoid bone

Cutaneous or nasal amyloidosis

Pulmonary tuberculosis

Pulmonary nocardiosis

Pneumocystis carinii pneumonia

5.5.1.1.6 UNCOMMON NONRESPIRATORY CAUSES

Lactation tetany

Hydroallantois or hydrops

Nutritional myodegeneration (foals)

Methemoglobin reductase deficiency

Acute hepatic insufficiency

Electrocution

Cardiac neoplasia

Embryonal mediastinal cyst

5.5.1.1.7 TOXIC CAUSES

α-Naphthyl thiourea (ANTU)

Arsenic

Bromide

Sodium fluoroacetate

Cantharidin (blister beetle)

Ammonia

Amitraz

Propylene glycol

Dioctyl sodium sulfosuccinate

Iron

Selenium

Metaldehyde

Organophosphate

Organochlorine, chlorinated hydrocarbon

Phenothiazine

Potassium

Larkspur (*Delphinium* species)

Japanese yew *(Taxus cuspidata)*

Bovine atypical interstitial pneumonia (B)

Acute pulmonary edema and emphysema (B)

Farmer's lung (*Faenia rectivirgula* hypersensitivity pneumonitis) (B)

Aspiration or foreign body pneumonia

5.5.1.2.2 COMMON NONRESPIRATORY CAUSES

Hyperthermia (fever, heat stroke, rapid rise in ambient temperature, other)

Pain (abdominal crisis, urethral calculi, traumatic reticuloperitonitis, musculoskeletal injury, other)

Acidosis (ruminal lactic acidosis, pregnancy toxemia, other)

Electrolyte aberrations (hypocalcemia, hypomagnesemia, other)

Shock (hypovolemic, cardiac, septic)

Anemia (iron deficiency, postparturient hemoglobinuria, blood loss, other)

Distended abdominal viscus (ruminal bloat, other)

Anaphylaxis

Blood transfusion reaction

White muscle disease

5.5.1.2.3 LESS COMMON RESPIRATORY CAUSES

Nasal trauma

Tumors of the nose and paranasal sinuses

Nasal granulomas (fungal granuloma, atopic rhinitis)

Congenital cystic nasal conchae

Laryngeal trauma, abscess

Tracheal stenosis, collapse, stricture

Bovine rhinovirus (B)

Bovine malignant catarrhal fever (B)

Ascaris suum migration (calves) (B)

Thoracic trauma, other causes of chest pain

Pneumothorax

Diaphragmatic hernia

Pleuritis or pleural effusion

Caprine arthritis-encephalitis (CAE) pneumonia (C)

Sheep pulmonary adenomatosis virus pneumonia (O)

5.5.1.2.4 LESS COMMON NONRESPIRATORY CAUSES

Cardiac anomalies (ventricular septal defect, tetralogy of Fallot, other)

Endocarditis

Pericarditis

Central nervous system disease (meningoencephalitis, polioencephalomalacia, other)

Esophageal obstruction or foreign body

Clostridial diseases (Black's disease, enterotoxemia, tetanus)

Anaphylaxis

5.5.1.2.5 UNCOMMON RESPIRATORY CAUSES

Pleural mesothelioma

Pneumocystis carinii pneumonia

Pulmonary aspergillosis

Pulmonary neoplasia

Cyst (branchial, cervical, thyroglossal duct) (B)

Bronchobiliary fistula

Contagious bovine pleuropneumonia (exotic) (B)

Endemic ethmoid carcinoma (exotic) (B)

5.5.1.2.6 UNCOMMON NONRESPIRATORY CAUSES

Bluetongue (B, O)

Thymic lymphosarcoma (B)

Retrobulbar neoplasia (B)

Calf lymphosarcoma (B)

Adult multicentric lymphosarcoma (B)

Embryonal mediastinal cyst

Dwarfism (B)

Anthrax

5.5.1.2.7

TOXIC CAUSES

Sodium fluoroacetate

Strychnine

Sulfur

Propylene glycol

Urea or nonprotein nitrogen

Water deprivation or salt toxicity

Potassium

Nitrates

Bromide

Iron

Selenium

Organophosphate

Organochlorine or chlorinated hydrocarbon

Larkspur (*Delphinium* species)

Japanese yew *(Taxus cuspidata)*

Sneezeweed *(Helenium autumnale)*

Hairy vetch *(Vicia villosa)*

Whitehead *(Sphenosciadium capitellatum)*

White snakeroot *(Eupatorium rugosum)*

B, Bovine; *C*, caprine; *O*, ovine.

Note: Tachypnea is a rather nonspecific sign and is associated with toxicity caused by a large number of plant species; only a few are listed in this box. See also Box 5-15, p. 65.

5.5.2

Pathophysiology

Normal respiratory rate and character are maintained by central and peripheral monitoring of blood gas and acid-base status, with resulting reflex adjustments that maintain carbon dioxide (CO_2), oxygen (O_2), and the blood hydrogen ion concentration (pH) within a narrow range.[71] Respiratory distress may occur for the following reasons[72]:

- Inadequate oxygenation of blood (i.e., a need for additional oxygen)
- Compensation for metabolic acidosis
- Excessive environmental heat
- Disorders that damage the central nervous system respiratory centers in the medulla (e.g., head trauma, inflammation, mass lesions) if they disrupt the control of breathing
- Disorders that cause dysfunction of motor nerves or weakness of respiratory muscles (e.g., botulism, polyradiculoneuritis, myasthenia gravis, or diaphragmatic paralysis)
- Painful conditions involving the respiratory sensory nerves, muscles, pleura, and ribs (e.g., chest trauma, pleural infection, or neoplasia)

Inadequate oxygenation of blood leads to arterial hypoxemia (low partial pressure of oxygen in arterial blood [Pa_{O_2}]). This can be caused by a low partial pressure of inspired oxygen (PI_{O_2}), such as occurs at high altitude; by disorders that interrupt the transfer of oxygen from the environment to the blood (e.g., upper and lower airway obstruction, pulmonary disease associated with alveolar flooding or collapse, and pulmonary or intracardiac right-to-left shunting of blood); or by a decrease in the oxygen-carrying capacity of the blood, such as occurs in anemia, methemoglobinemia, and carboxyhemoglobinemia.[72] Primary or secondary disease conditions that affect the respiratory and cardiovascular systems induce arterial hypoxemia by causing alveolar hypoventilation, ventilation-perfusion mismatch, diffusion limitation, right-to-left shunting of blood, or combinations of these abnormalities (see Cyanosis, p. 68).[68,72]

Compensation for metabolic acidosis involves “blowing off” carbon dioxide, which may increase both the rate and depth of respiration.[72] The resulting hyperventilation causes a decline in the partial pressure of arterial carbon dioxide (Pa_{CO_2}) in the face of clinical signs of respiratory distress.

Animals dissipate a considerable amount of heat through the respiratory tract. In ruminants, but not in horses, heat dissipation is further aided by the animals' ability to mouth breathe and pant to increase evaporative cooling of blood passing through the tongue and other structures in the oral cavity and oropharynx. The need to dissipate heat when exposed to high environmental temperatures induces labored breathing (Boxes 5-14 and 5-15).

Apparent respiratory distress also occurs when the weather is not excessively hot but the temperature has risen rapidly, such as occurs when cattle in cold climates are brought indoors in the winter. When the environmental temperature has been consistently low, cattle in feedlots may also experience respiratory distress if the temperature suddenly rises to 4.4° to 10°C (40° to 50°F).

Observation of the nature of the respiratory distress may give important clues as to the functional characterization, and perhaps cause, of the underlying disease process. Obstructive diseases involving the intrathoracic airways (e.g., RAO in horses and farmer's lung in cattle) are more likely to cause flow limitation during expiration because of dynamic airway narrowing or collapse (see Cough, p. 42).[68,73,74] This results in expiratory respiratory distress and a pattern of respiration in which the expiratory phase occupies an increased proportion of the respiratory cycle as the patient attempts to expel air from the lungs.[68] In the extrathoracic airways, dynamic collapse occurs during inspiration because intraluminal pressures are subatmospheric at this time.[68,73,74] Therefore patients with upper airway obstructions, especially of the nonfixed type (e.g., laryngeal hemiplegia), generally show inspiratory respiratory distress and may have a prolonged inspiratory phase.[68,73] Fixed airway obstructions of either the upper or lower airway (e.g., intraluminal mass, bronchoconstriction) are present during both phases of respiration and may lead to both inspiratory and expiratory distress.[68] However, the distress is likely to be accentuated during a particular phase of respiration, depending on the anatomic site of the obstruction (i.e., fixed upper airway obstructions cause more distress during inspiration, and fixed lower airway obstructions cause more distress during expiration). Restrictive diseases (e.g., pleural effusion, pneumoconiosis) inhibit expansion of the lungs and therefore generally lead to inspiratory respiratory distress.[68] Because an animal with restrictive disease has reduced compliance and must perform more respiratory work than normal to expand its lungs, a common strategy for maintaining adequate ventilation is to increase the respiratory rate and lower the tidal volume (i.e., rapid, shallow breathing).[68] Animals with obstructive diseases generally have a normal or even increased tidal volume.[68]

In many instances, respiratory distress is not apparent at rest but occurs in association with exercise. Under these circumstances the animal's capacity to exercise is impaired, and the owner may complain of exercise intolerance (see Exercise Intolerance and Poor Performance in Horses, p. 76).

5.5.3 Approach to Diagnosis of Respiratory Distress

5.5.3.1 HISTORY

After ruling out environmental causes of respiratory distress (e.g., heat stress, high humidity, moving from outside into a heated barn in the winter, handling stress, or relocation to high altitude) and attending to the immediate needs of the patient, a careful history should be taken that includes the following factors: time and speed of onset of the clinical signs of respiratory distress; progression of clinical signs; whether this is the first episode of respiratory distress or whether the animal is subject to recurrent attacks; whether signs are present at rest or only after exercise; the relationship of signs to environmental conditions and the response to environmental change; recent administration of pharmacologic or biologic agents; the presence of an audible respiratory noise; or other signs of respiratory tract, oropharyngeal, or neurologic disease (e.g., nasal discharge, cough, dysphagia, facial paralysis, or retropharyngeal swelling). A history of recent trauma or exposure to potentially toxic substances, such as lead-containing paints, nitrate-accumulating plants or urea (ruminants), or carbon monoxide, should be elicited. The animal's appetite and attitude and signs of disease in other systems (e.g., diarrhea) should be determined. In neonates the circumstances surrounding gestation and parturition should be ascertained, because prematurity, dysmaturity, congenital infection, birth trauma (e.g., rib fracture)

related to dystocia, prolonged parturition, and aspiration of amniotic fluid and meconium are all important causes of respiratory distress. However, it should be noted that tachypnea, with respiratory rates of 60 to 80 breaths/min, is normal in foals during the first 30 minutes after birth as they "blow off" carbon dioxide (see Disorders and Management of the Neonate, Chapter 15 and Chapter 19). 66

5.5.3.1.1

Box 5-14 Causes of Respiratory Distress in Horses

5.5.3.1.1.1

COMMON RESPIRATORY CAUSES

Bacterial pneumonia

Pleuropneumonia Pleuritis

Pulmonary abscessation

Recurrent airway obstruction (housing or pasture associated)

Strangles (*Streptococcus equi* infection)

Viral pneumonia (influenza, adenovirus, equine viral arteritis, others)

Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)

Aspiration pneumonia

Prematurity, dysmaturity, immaturity (foals)

Neonatal septicemia (foals)

Pharyngeal, retropharyngeal abscess or trauma

5.5.3.1.1.2

COMMON NONRESPIRATORY CAUSES

Cardiac disease (e.g., congestive cardiac failure, mitral insufficiency, other cardiac diseases)

Shock (septic, cardiogenic, hypovolemic, acute blood loss)

Endotoxemia

Anemia (e.g., neonatal isoerythrolysis, autoimmune hemolytic anemia, blood loss, other causes of acute anemia)

Pain (e.g., abdominal crisis, laminitis, myopathy, fracture, other lameness)

Hyperthermia (e.g., fever, postexhaustion syndrome, anhidrosis, heat stroke, erythromycin associated)

5.5.3.1.1.3

LESS COMMON RESPIRATORY CAUSES

Epiglottic entrapment with secondary infection or granulation

Arytenoid chondritis

Guttural pouch empyema, tympany, mycosis, neoplasia

Progressive ethmoid hematoma

Nasal polyps

Pharyngeal, subepiglottic cysts

Fungal rhinitis, cryptococcal rhinitis, equine nasal granuloma, nasal aspergillosis, rhinosporidiosis, rhinophycomycosis, maduromycosis, mycetoma

Cleft palate

Laryngeal or hyoid trauma, fractured laryngeal cartilages, laryngeal granuloma or scar

Paranasal sinus infection, cyst, trauma, tumor

Nasal trauma, nasal neoplasia

Foreign body (nasal, pharyngeal, laryngeal, tracheal, bronchial)

Exercise-induced pulmonary hemorrhage (EIPH)

Parasitic pneumonia *(Dictyocaulus arnfieldi)*

Coccidioidomycosis, cryptococcosis, mycotic pneumonia

Inhalation pneumonia, smoke inhalation, drowning, water inhalation

Hyaline membrane disease (foals)

Acute bronchointerstitial pneumonia

Peripartum asphyxia syndrome

Fractured ribs or sternum, thoracic trauma

Pneumothorax

Diaphragmatic hernia

Mediastinal abscess

5.5.3.1.1.4

LESS COMMON NONRESPIRATORY CAUSES

Purpura hemorrhagica

Blood or plasma transfusion reaction

Complications of fluid therapy

Anaphylaxis

Intracarotid injection

Acidosis

Gastric distention (e.g., as in small intestinal obstruction)

Pulmonary edema

Malignant hyperthermia

Cardiovascular anomalies (ventricular septal defect, patent ductus arteriosus, tetralogy of Fallot, common ventricle, other anomalies)

Endocarditis

Pericarditis

Cardiac dysrhythmias (atrial fibrillation, heart block, ventricular premature beats, ventricular tachycardia, ventricular fibrillation)

Ruptured mitral chordae tendineae

Mitral insufficiency or stenosis

Clostridial infections (e.g., tetanus, malignant edema, injection abscess)

Procaine penicillin G reaction or intravascular administration

Hyperkalemic periodic paralysis (HYPP)

5.5.3.1.1.5

UNCOMMON RESPIRATORY CAUSES

Stenotic external nares

Cutaneous, nasal amyloidosis

Cutaneous, nasal habronemiasis (summer sore)

Failure of closure of the false nostril

Abnormalities of the nasal septum

Choanal (posterior nares) atresia or stenosis (foals)

Nasopharyngeal cicatrix

Laryngopalatal dislocation (dorsal displacement of soft palate), soft palate hypoplasia

Rostral displacement of the palatopharyngeal folds

Pharyngeal hematoma

Laryngeal paralysis

Fistula (pharyngeal, esophageal, esophagobronchial, esophagotracheal)

Chondroma of the arytenoid cartilage

Laryngeal spasm

Hypertrophic ossification of the laryngeal cartilages, laryngeal chondropathy

Neoplasia of the upper airway

Tracheal stenosis, stricture, collapse, rupture

Phycomycosis, pythiosis

Pneumoconiosis (e.g., silicosis)

Interstitial pneumonia (restrictive pulmonary disease)

Pulmonary thromboembolism

Pneumocystis carinii pneumonia

Pulmonary lobar hypertrophy (foals)

Infarctive lobar pneumonia

Chlamydia psittaci pneumonia

Pulmonary nocardiosis

Pulmonary tuberculosis

Pulmonary aspergillosis

Besnoitiosis *(Besnoitia besnoiti* and *Besnoitia jellisoni)*

Pulmonary neoplasia (primary or metastatic)

Pleural neoplasia (mesothelioma, lymphosarcoma)

Embryonic cyst (mediastinal, branchial, cervical, thyroglossal duct)

Morbillivirus infection (exotic)

5.5.3.1.1.6

UNCOMMON NONRESPIRATORY CAUSES

Nutritional myodegeneration

Lactation tetany (eclampsia)

Hydroallantois or hydramnios

Methemoglobin reductase deficiency

Hemophilia A (factor VIII deficiency)

Acute hepatic insufficiency

Electrocution

Cor pulmonale

Neoplasia (all systems)

Snake or insect bite

Aortoiliofemoral thrombosis

Equine motor neuron disease

Cholesteremic granuloma

5.5.3.1.1.7 TOXIC CAUSES

Vitamin D

Lead

Organophosphate-associated laryngeal paralysis

Monensin, lasalocid, salinomycin

Propylene glycol

Iron

Dinitrophenol

Selenium

Bromide

Sodium fluoroacetate

Strychnine

Ammonia

Theobromine, chocolate

Cantharidin (blister beetle)

α-Naphthyl thiourea (ANTU)

Red maple *(Acer rubrum)*

Water hemlock (*Cicuta* species)

Oleander *(Nerium oleander)*

Japanese yew *(Taxus cuspidata)*

Larkspur (*Delphinium* species)

Ryegrass (*Lolium* species)

White snakeroot *(Eupatorium rugosum)*

Crofton weed *(Eupatorium adenophorum)*

Pyrrolizidine alkaloid

Locoweeds (*Astragalus* species, *Oxytropis* species)

Avocado *(Persea americana)*

Hoary alyssum *(Berteroa incana)*

Coffee senna seed *(Cassia occidentalis)*

Rubber vine *(Cryptostegia grandiflora)*

Birdsville disease (*Indigofera* species) (exotic)

Trachyandra paralysis (exotic)

5.5.3.1.2

Box 5-15 Causes of Respiratory Distress in Ruminants

5.5.3.1.2.1

COMMON RESPIRATORY CAUSES

Mannheimia hemolytica or *Pasteurella multocida* pneumonia (includes shipping fever and enzootic calf pneumonia)

Bacterial pneumonia with consolidation or abscessation (*Arcanobacterium [Actinomyces]* and other bacteria)

Haemophilus somnus pneumonia (B)

Visceral caseous lymphadenitis *(Corynebacterium pseudotuberculosis)* (O, C)

Aspiration or foreign body pneumonia (especially after hypocalcemia)

Necrotic laryngitis *(Fusobacterium necrophorum)* (B, O)

Infectious bovine rhinotracheitis virus (IBR; BHV-1) (B)

Respiratory syncytial virus

Ovine progressive pneumonia virus (O)

Mycoplasma mycoides subsp. *mycoides, Mycoplasma agalactiae*, other *Mycoplasma* species (C)

Mycoplasma ovipneumoniae (O)

Parasitic pneumonia (*Dictyocaulus viviparus* [B], *Dictyocaulus filaria* [O, C], *Müllerius capillaris* [O, C], *Protostrongylus rufescens* [O, C])

Bovine atypical interstitial pneumonia (B)

Acute bovine pulmonary edema and emphysema (B)

Farmer's lung disease (*Faenia rectivirgula* hypersensitivity pneumonitis) (B)

5.5.3.1.2.2

COMMON NONRESPIRATORY CAUSES

Hyperthermia (fever, heat stroke, rapid rise in ambient temperature, other)

Pain (abdominal crisis, urethral calculi, traumatic reticuloperitonitis, other)

Distended abdominal viscus

Acidosis (ruminal lactic acidosis, pregnancy toxemia, other)

Electrolyte aberrations (hypocalcemia, hypomagnesemia, other)

Hypovolemic, cardiac, or septic shock

Fluid or electrolyte loss (acute diarrhea, gastrointestinal obstruction, other)

Endotoxemia (coliform mastitis, metritis, enteritis, salmonellosis, septicemia, other)

Neonatal septicemia

Anemia (iron deficiency, postparturient hemoglobinuria, hemolytic, anaplasmosis, eperythrozoonosis, other)

White muscle disease (nutritional myodegeneration)

Anaphylaxis or allergy, milk allergy

5.5.3.1.2.3

LESS COMMON RESPIRATORY CAUSES

Pulmonary embolus from posterior vena cava thrombosis (B)

Parainfluenza virus type 3

Adenovirus (B, O)

Nasal trauma

Tumors of the nose, paranasal sinuses, oral cavity

Nasal granulomas (fungal granuloma, atopic rhinitis)

Congenital cystic nasal conchae

Nose bots *(Oestrus ovis)*

Sinusitis (maxillary, frontal, postdehorning)

Laryngeal trauma or abscess

Trauma (oral, pharyngeal, retropharyngeal), abscess, hematoma

Tracheal stenosis, collapse, stricture

Bovine rhinovirus (B)

Bovine malignant catarrhal fever (B)

Bovine herpesvirus DN-599 (B)

Ascaris suum migration (calves) (B)

Thoracic trauma, rib fracture

Pneumothorax

Pleuritis or pleural effusion

Caprine arthritis-encephalitis (CAE) pneumonia (C)

Sheep pulmonary adenomatosis virus (Jaagsiekte) (O)

Smoke inhalation

Foreign body (nasal, oral, pharyngeal, laryngeal, tracheal, bronchial)

Caprine herpesvirus (C)

Bluetongue

Peste des petits ruminants (C, O) (exotic)

Congenital cardiac anomalies (ventricular septal defect, tetralogy of Fallot, patent ductus arteriosus, transposition of the great vessels, other anomalies)

Acquired cardiac failure (bacterial endocarditis, valvular incompetence, valvular stenosis, cardiomyopathy, pericarditis, other causes)

Central nervous system disease (trauma, meningoencephalitis, encephalomalacia, abscess, louping ill, pseudorabies, other causes)

Esophageal obstruction, foreign body, laceration, rupture, megaesophagus

Clostridial diseases (Black's disease, enterotoxemia, tetanus, blackleg, bacillary hemoglobinuria, others)

Anthrax

Complications of fluid therapy (pulmonary edema)

Water deprivation (salt poisoning) (B)

Blood transfusion reaction

Anaphylaxis

Burn, thermal injury, electrocution

Systemic toxoplasmosis (C, O)

Tick paralysis (C, O)

Bladder rupture

Bee or wasp sting, snakebite

Photosensitization

5.5.3.1.2.4

UNCOMMON RESPIRATORY CAUSES

Actinobacillosis (wooden tongue)

Actinomycosis (lumpy jaw)

Diaphragmatic hernia

Pleural mesothelioma

Pneumocystis carinii pneumonia

Pulmonary aspergillosis

Pulmonary neoplasia

Pulmonary tuberculosis

Chlamydia psittaci pneumonia

Cyst (branchial, cervical, salivary, thyroglossal duct)

Bronchobiliary fistula

Contagious bovine pleuropneumonia (exotic) (B)

Endemic ethmoid carcinoma (exotic) (B)

Theileria annulata and *Theileria hirci* (exotic) (B)

Heartwater *(Cowdria ruminatum)* (exotic)

5.5.3.1.2.5

UNCOMMON NONRESPIRATORY CAUSES

Retrobulbar neoplasia (B)

Enzootic bovine leukosis (B)

Thymic lymphosarcoma or thymoma

Calf lymphosarcoma (B)

Adult multicentric lymphosarcoma (B)

Embryonal mediastinal cyst

Dwarfism (B)

Botulism

Vesicular stomatitis

High altitude (brisket) disease, cor pulmonale (B, C)

Procaine penicillin G reaction or intravascular administration

Liver disease (infectious, toxic, parasitic, other)

Border disease (hairy shaker) (C, O)

5.5.3.1.2.6

TOXIC CAUSES

Sodium fluoroacetate

Strychnine

Sulfur (B, O)

Propylene glycol (B)

Oxalate, ethylene glycol (B, O)

Urea or nonprotein nitrogen

Potassium (B)

Nitrates

Bromide (B, C)

Lead

Mercury (C)

Iron (B, C)

Selenium

Arsenic

Organophosphate or carbamate

Organochlorine or chlorinated hydrocarbon

Permethrin

Gossypol

Ergot *(Claviceps purpura)*

Phosphate fertilizer (B, O)

Vitamin D_3 (B)

Warfarin, dicumarol, diphacinone

Metaldehyde

Formaldehyde

Ammonia

Hydrogen sulfide

Monensin, salinomycin

Dinitrophenol (B, O)

Copper (acute oral toxicity)

Insect fogger pneumonitis (B)

Aflatoxicosis (C)

Levamisole (C, O)

Polychlorinated biphenyl (PCB) (B)

Xylazine-induced pulmonary edema (O)

Carbolic dips (O)

Cyanogenic plants (arrow grass, Johnson grass, common sorghum, Sudan grass, chokecherry, acacia, other plants)

Avocado *(Persia americana)*

Moldy sweet clover (*Melilotus* species)

Moldy sweet potato *(Ipomoea batatas)* (B)

Brassica species

Ryegrass (*Lolium* species) (B, O)

Larkspur (*Delphinium* species)

Japanese yew *(Taxus cuspidata)*

Hairy vetch *(Vicia villosa)* (B)

Whitehead *(Sphenosciadium capitellatum)* (B)

White snakeroot *(Eupatorium rugosum)* (B, O)

Chinese tallow *(Sapium sebiferum)* (B)

Purple mint *(Perilla frutescens)* (B)

Oleander *(Nerium oleander)*

Nightshade (*Solanum* species) (B)

Cocklebur (*Xanthium* species) (B, O)

Locoweeds (*Astragalus* species, *Oxytropis* species) (B, O)

Foxglove *(Digitalis purpurea)* (B)

Water hemlock (*Cicuta* species)

Milkweed (*Asclepias* species) (B, O)

Hepatotoxic plants (*Senecio* species, *Amsinckia* species, others containing pyrrolizidine alkaloid)

Fescue summer poisoning (B)

Rubberweed (*Hymenoxys* species)

Sneezeweed *(Helenium autumnale)*

False hellebore (*Veratrum* species) (B, O)

Rhododendron (*Andromeda* species) (B, O)

Algae

Lupines (*Lupinus* species) (B, O)

Prickly paddy melon *(Cucumis myriocarpus)*

B, Bovine; *C*, caprine; *O*, ovine.

Note: Respiratory distress is a sign associated with toxicity caused by a large number of plant species. Not all have been listed here.

5.5.3.2

PHYSICAL EXAMINATION

The physical examination should follow the same general approach as that described for cough. In particular, the following should be determined: rectal temperature, pulse rate, respiratory rate and character; regularity and pattern of breathing; presence of excessive intercostal or abdominal respiratory effort; synchrony and symmetry of chest excursion; presence of a “heave line”; presence of stridor at rest (the examiner listens at the nostrils); symmetry of airflow from each nostril; effect of occlusion of each nostril independently; odor from the nose or mouth (or both); presence and character of nasal discharge; swelling around the external nares, inside the nasal passages, or inside the false nostril; facial symmetry and swelling; ocular discharge; resonance or painful response on percussion of the maxillary and frontal sinuses; palpable abnormalities of the mandibles and hyoid apparatus; enlargement of submandibular, parotid, retropharyngeal, and other regional lymph nodes; enlargement of the parotid salivary glands or thyroid gland; swelling, pain, or palpable abnormalities in the retropharyngeal region; a palpable, left-sided pit on the dorsal surface of the larynx; accentuation of stridor, induction of a cough, or evidence of pain on application of pressure to the larynx and trachea; palpable swelling or flattening of the cervical trachea; masses at the thoracic inlet; and palpable turbulence in the extrathoracic airway.

66

67

The mucous membranes should be examined carefully for cyanosis, pallor, cherry red color, hemorrhages, congestion, or injection. The capillary refill time should be determined, and the peripheral pulse rate, rhythm, and character should be assessed. Other signs of heart failure (e.g., jugular distention or pulsation and peripheral edema) and signs of dehydration (e.g., delayed jugular filling, dry mucous membranes, and altered skin turgor) should be noted. The larynx, trachea, and lungs should be carefully *auscultated* at rest and after the rate and depth of respiration have been increased, if it is safe to do so, by application of a rebreathing bag, by occlusion of the nostrils, or by exercising the animal, so that turbulent airflow and abnormal lung sounds may be detected. The heart should be auscultated to detect murmurs, cardiac dysrhythmias, muffling of heart sounds, or other abnormalities. The chest wall should be carefully *palpated* to detect rib fractures and other lesions; and both sides of the chest should be *percussed* to detect large mass lesions, lung consolidation, pleural

effusion, hyperinflation, pneumothorax, or a painful response, which may indicate pleuritis. A thorough oral examination is important, and in cattle this should include palpation of the base of the tongue, the oropharynx, and, if possible, the larynx (see Nasal Discharge, p. 50).

A general physical examination should be completed so that diseases in systems other than the cardiovascular and respiratory systems (e.g., respiratory distress in cattle secondary to ruminal bloat and respiratory distress secondary to central nervous system trauma or severe metabolic acidosis) can be detected. Attempts should also be made to identify conditions that may cause severe acid-base disturbances and hemoconcentration (e.g., diarrhea, renal disease), pain (e.g., laminitis or trauma), or hyperthermia (e.g., infectious conditions or heat stroke).

Further diagnostic evaluation of respiratory distress may include a complete blood count with fibrinogen concentration; blood gas analysis; serum biochemistry determinations; endoscopy of the upper and lower airways and esophagus; nasal or nasopharyngeal swabbing or scraping; virus identification, isolation, and serologic testing; bronchodilator response testing; tracheal aspiration; BAL; ultrasound examination of the chest and of suspected mass lesions that impinge on the upper airway; thoracocentesis; radiography of the nasal passages, paranasal sinuses, pharynx, guttural pouches, larynx, trachea, and chest; fecal examination for lungworms and other parasites; CT scanning of the upper airway; nuclear scintigraphy; pulmonary function testing; and biopsy of externally visible or palpable lesions or those identified by ultrasound, endoscopy, or radiography as described for the evaluation of cough and nasal discharge (see Cough, p. 42, and Nasal Discharge, p. 50).

5.5.3.3

COMPLETE BLOOD COUNT

A complete blood count, including fibrinogen and plasma protein concentrations, helps evaluate the role of hemoconcentration, anemia, or leukocytosis and hyperfibrinogenemia, which may accompany pneumonia and other inflammatory conditions.

5.5.3.4

ENDOSCOPIC EXAMINATION

Endoscopic examination of the upper and lower airways using fiberoptic or video endoscopes is particularly helpful in evaluating patients suspected of having obstructive disease[75] (see Cough, p. 42; Nasal Discharge, p. 50; and Stridor, p. 71). Endoscopic examination of the esophagus is indicated in patients with a history of bloat, dysphagia, or return of ingesta through the nose in addition to respiratory distress (see Nasal Discharge, p. 50, and Stridor, p. 71).

5.5.3.5

BLOOD GAS ANALYSIS

Blood gas analysis and acid-base determinations should be performed on arterial blood to determine O_2 and CO_2 tensions so that the contribution of hypoxemia or acidosis to the signs of respiratory distress can be ascertained. In foals and calves, arterial samples usually are obtained from the great metatarsal artery or the brachial artery as it crosses the medial aspect of the foreleg.[76] The auricular artery is also convenient in calves. The femoral artery can be used in neonates but is less convenient because it has a tendency to roll. The facial artery can be used in adult horses, and the auricular or coccygeal artery can be used in mature ruminants.[77] During the sampling process the patient should be quiet and not struggling, which can decrease the $PaCO_2$.[78] Local subcutaneous infiltration of 2% lidocaine without epinephrine over the artery being sampled minimizes

needless struggling and facilitates sample collection. A heparinized syringe and a 22- to 26-gauge needle can be used. Any air bubbles should be removed after sample collection and the needle properly sealed. If the sample is kept on ice, the pH will remain unchanged for 3½ hours and the blood gases for 6 hours.[79] The animal's temperature should be recorded at the time of sample collection so that it can be used in the calculation of actual blood gas concentrations.

The normal Pa_{O_2} for the horse is 83.6 ± 1.7mm Hg, and the normal Pa_{CO_2} is 42.2 ± 0.8mm Hg.[57] Hypoxemia is defined as a Pa_{O_2} below 80mm Hg.[80] Cyanosis is usually not evident until the Pa_{O_2} is much lower than this (usually below 40mm Hg).[80] Hypercarbia, or hypercapnia, is a condition of increased Pa_{CO_2} (above 44mm Hg).[80] Because CO_2 diffuses readily, considerable ventilatory dysfunction can occur before the Pa_{CO_2} rises; therefore severe hypoxemia can occur with a normal Pa_{CO_2}. An elevated Pa_{CO_2} generally indicates that hypoventilation or a severe pulmonic pathologic condition is present. Because venous blood samples reflect tissue metabolism, they are not considered adequate for evaluating pulmonary function. However, a partial pressure of carbon dioxide in venous blood (Pv_{CO_2}) above 60mm Hg usually reflects arterial hypercapnia, and a partial pressure of oxygen in venous blood (Pv_{O_2}) below 20mm Hg usually indicates arterial hypoxemia.[79]

Venous admixture is the term used to denote the ways that blood can pass from the right side to the left side of the circulation without being properly oxygenated and represents the efficiency with which the lung oxygenates blood. The magnitude of venous admixture (efficiency of oxygenation) can be assessed by calculating the Pa_{O_2}/Fi_{O_2} ratio or the alveolar-arterial P_{O_2} gradient. The Pa_{O_2}/Fi_{O_2} ratio is normally 500. Pa_{O_2}/Fi_{O_2} ratios between 300 and 400 reflect significant lung injury, values below 300 reflect profoundly inefficient lung function such as occurs with acute lung injury, and values below 200 reflect severe life-threatening lung disease typical of acute respiratory distress syndrome (ARDS). The alveolar-arterial (A-a) P_{O_2} gradient difference is the difference between calculated alveolar P_{O_2} and the measured arterial P_{O_2}. Alveolar P_{O_2} = Inspired P_{O_2} − Pa_{CO_2} (1.1), where inspired P_{O_2} = barometric pressure × 21% and 1.1 = 1/RQ, where RQ is the respiratory quotient and has an assumed value of 0.9. The A-a P_{O_2} difference is typically about 10mm Hg in a normal horse breathing 21% oxygen (room air) at sea level and about 100mm Hg when breathing 100% oxygen. The “120 rule” is a simplified version of the alveolar gas equation that can be applied to a patient breathing 21% oxygen at near sea level. The measured Pa_{O_2} and Pa_{CO_2} should add up to 140 ± 10. If the sum is less than 120, the patient has venous admixture; and the lower the value, the worse the admixture.

67

68

5.5.3.6

INSUFFLATION OF 100% OXYGEN

Insufflation of 100% oxygen causes a significant increase in Pa_{O_2} if hypoxemia is caused by hypoventilation or ventilation-perfusion mismatch, whereas little or no improvement in Pa_{O_2} occurs if hypoxemia is caused by anatomic or physiologic right-to-left shunting.[68] Therefore measuring Pa_{O_2} 5 minutes after insufflation of 100% oxygen can help in determining the pathophysiologic processes contributing to arterial hypoxemia. In full-term neonates and adults the Pa_{O_2} should exceed 200mm Hg after 5 minutes of oxygen administration.[78] Continued cyanosis or inability to raise the Pa_{O_2} above 100mm Hg is highly suggestive of a right-to-left shunt.

5.5.3.7 DETECTION OF ABNORMAL HEMOGLOBIN

Blood samples should be evaluated for abnormal hemoglobin (e.g., methemoglobin) and also if exposure to nitrates or similar toxins is suspected (see Cyanosis, p. 68).

5.5.3.8 RADIOGRAPHIC EXAMINATION

Radiographic examination of the nasal passages, pharynx, larynx, and trachea permits detection and evaluation of obstructive lesions in the upper airway, especially if tachypnea is accompanied by inspiratory stridor, asymmetric nasal airflow, or other evidence of upper airway obstruction.

Radiographic examination of the trachea and thorax should include end-inspiratory phase radiographs to facilitate identification of pulmonary lesions and disorders such as dynamic collapse of the trachea that are visible only on inspiratory-phase radiographs. Chest radiographs help detect evidence of pneumonia, pleural effusion, pneumothorax, cardiomegaly, and mediastinal lesions. The cardiac silhouette and the pattern and caliber of the aorta, vena cava, pulmonary artery, pulmonary veins, and other vessels should also be evaluated for evidence of cardiac failure and pulmonary vascular disease. *Contrast angiography* and other diagnostic procedures, such as *echocardiography, electrocardiography*, and *hemodynamic (pressure and flow) studies*, may be indicated in patients with respiratory distress that has occurred secondary to cardiovascular disease.

5.5.3.9 ULTRASOUND EXAMINATION

Ultrasound examination of the thorax is performed to detect pleural inflammation and effusion, pulmonary consolidation, pulmonary abscessation, and cardiac anomalies if the clinical examination suggests that pulmonary, pleural, or cardiac disease is the cause of the signs of respiratory distress.

5.6 CYANOSIS

5.6.1 Definition

Cyanosis is the bluish discoloration of skin, conjunctivae, and visible mucous membranes that results from an increase in the absolute amount of reduced hemoglobin in the blood.[81]

5.6.2 Pathophysiology

Oxygen is carried in blood in two forms, dissolved and in combination with hemoglobin (Hb). The amount of dissolved oxygen present in arterial blood is relatively small and is proportional to the Pa_{O_2}. Oxygen transport to tissues is facilitated by the ability of hemoglobin in erythrocytes to combine in a reversible manner with oxygen. When erythrocytes pass through the pulmonary circulation, oxygen binds to hemoglobin, forming oxyhemoglobin (HbO_2). As oxyhemoglobin passes through systemic capillaries, oxygen diffuses into tissues, and hemoglobin is once again formed.

The Bohr effect describes the ability of hemoglobin to bind to a number of different ligands (CO_2, H^+, and 2,3-diphosphoglycerate [2,3-DPG]), which results in modification of hemoglobin's affinity for oxygen. When tissue

pH decreases, hemoglobin acts as a buffer and binds excess H^+, which decreases its affinity for oxygen. When the CO_2 concentration increases, some CO_2 is converted to bicarbonate and the remainder is bound to hemoglobin to form carbaminohemoglobin; this also decreases the affinity of hemoglobin for oxygen. Therefore the net effect of a decreased blood pH and increased blood CO_2 concentration is unloading of oxygen to the tissues. Conversely, as the CO_2 concentration in the pulmonary capillaries decreases and blood pH rises, the affinity of hemoglobin for oxygen increases; thus the net effect of elevated blood pH in pulmonary capillaries is increased uptake of oxygen by hemoglobin.

The affinity of hemoglobin for oxygen is also influenced by the concentration of 2,3-DPG, a metabolic intermediate of the Rappaport-Luebering shunt involved in erythrocyte glycolysis. An increase in the 2,3-DPG concentration may occur in association with chronic hypoxemia (high altitude, chronic lung disease), anemia, chronic alkalosis, phosphate retention, and red cell pyruvate kinase deficiency. When the 2,3-DPG concentration is increased, the affinity of hemoglobin for oxygen is decreased, resulting in improved unloading of oxygen to peripheral tissues. Conversely, a decreased 2,3-DPG level results in an increased affinity of hemoglobin for oxygen. A decrease in the 2,3-DPG concentration may occur in stored blood, in association with chronic acidosis, and with hypophosphatemia.

Cyanosis develops when the oxygen saturation of hemoglobin is below 80%. With a normal oxygen-hemoglobin dissociation curve, the Pa_{O_2} usually is below 40mm Hg before cyanosis is noted in the patient.[82] The hemoglobin concentration of blood must be near normal for cyanosis to be clinically evident[83]; therefore patients with severe anemia and concomitant marked arterial oxygen desaturation may not show cyanosis. In contrast, patients with marked polycythemia may be cyanotic at a higher arterial oxygen saturation than patients with normal hematocrit values.

5.6.3 Classification

Cyanosis can be classified as either *peripheral* or *central*.

5.6.3.1 PERIPHERAL CYANOSIS

Peripheral cyanosis is caused by slowing of blood flow to an area, resulting in abnormally increased extraction of oxygen from normally saturated arterial blood. Decreased blood flow through the peripheral capillary bed may be caused by vasoconstriction of superficial vessels, obstruction of arteries or veins, or low cardiac output. Peripheral cyanosis is observed in the extremities, nose, and ears and usually is not associated with cyanosis of mucous membranes. Peripheral cyanosis is rarely recognized in large domestic animals because of their skin pigmentation and hair cover.

5.6.3.2 CENTRAL CYANOSIS

68

Central cyanosis results from either inadequate oxygenation of arterial blood or from the presence of an abnormal hemoglobin derivative and is characterized by cyanosis of mucous membranes (Table 5-1). Causes of inadequate oxygenation of arterial blood are respiratory diseases or congenital cardiac anomalies that cause right-to-left shunting (Boxes 5-16 and 5-17). Acquired abnormalities of hemoglobin function can be induced by a number of chemicals. Exposure to these chemicals results in the formation of methemoglobin or sulfhemoglobin, neither of which is capable of binding oxygen. Nitrites and nitrates are powerful reducing agents that produce methemoglobinemia by directly oxidizing hemoglobin to methemoglobin. Nitrate

69

poisoning is most commonly associated with the incorporation of nitrate-accumulating plants (e.g., pigweed *[Amaranthus retroflexus]*, lamb's-quarters *[Chenopodium album]*, and mintweed *[Salvia reflexa]*) in livestock forage. Nitrate intoxication usually is seen only in ruminants because rumen microorganisms reduce nitrate to the more toxic nitrite ion. Congenital defects in hemoglobin function have been reported in humans and may occur in large domestic animals. Examples of such defects are nicotinamide adenine dinucleotide methemoglobin reductase deficiency and familial methemoglobinemia.

Table 5-1 Pathophysiologic Classification of Central Cyanosis and Examples of Associated Conditions

Classification	Associated Condition
Decreased arterial oxygen saturation	Respiratory disease Ventilation-perfusion mismatch Alveolar hypoventilation Impaired oxygen diffusion Pulmonary arteriovenous shunting Cardiac disease Cardiac anomalies that cause right-to-left shunting (e.g., tetralogy of Fallot)
Abnormal hemoglobin derivative	Methemoglobinemia Sulfhemoglobinemia

5.6.4

Conditions That Predispose to Hypoxemia and Central Cyanosis

The remainder of this section is confined to the discussion of respiratory conditions and cardiovascular anomalies that predispose to hypoxemia and central cyanosis. Impaired pulmonary function may cause hypoxemia and, in some circumstances, cyanosis. Mechanisms by which hypoxemia of pulmonary origin can arise include alveolar hypoventilation, reduced gas transfer or diffusion across the blood-gas barrier, ventilation-perfusion mismatch, pulmonary arteriovenous shunt, or a combination of these factors.[81,83] An additional cause of hypoxemia is the decrease in the partial pressure of alveolar oxygen that occurs at high altitudes.

5.6.4.1

ALVEOLAR HYPOVENTILATION

Alveolar hypoventilation is defined as a reduced volume of inspired air reaching the alveoli per unit time. Alveolar hypoventilation is always associated with an increased $PaCO_2$. Conditions associated with alveolar hypoventilation are drug-induced respiratory depression (morphine, barbiturates), brainstem disease (encephalitis, trauma, hemorrhage, neoplasia), and transection of the cervical spinal cord. All these conditions prevent proper generation and transmission of signals from the respiratory center to respiratory muscles. Other possible causes of alveolar hypoventilation are abnormal respiratory muscle function (diaphragmatic hernia, botulism), thoracic cage abnormalities (rib fracture), increased airway resistance (e.g., stenotic nares, laryngeal stricture or paresis, foreign body obstruction, bronchitis, bronchiectasis), and pleural space disease (inflammatory or neoplastic effusions, pneumothorax, hydrothorax, chylothorax, pyothorax, hemothorax).

69

70

5.6.4.1.1

Box 5-16 Causes of Central Cyanosis in Horses

5.6.4.1.1.1

COMMON CAUSES

Bacterial pneumonia, pleuritis, pulmonary abscessation (*Rhodococcus equi, Streptococcus* species, other bacteria)

Recurrent airway obstruction (RAO or COPD)

Aspiration pneumonia

Viral pneumonia (equine influenza, adenovirus, other viruses)

Equine herpesvirus types 1 and 4 (EHV-1, EHV-4)

Acute bronchointerstitial pneumonia

Prematurity, dysmaturity, immaturity (foals)

Ventricular septal defect with pulmonary hypertension

Tetralogy of Fallot

Toxic methemoglobinemia

Anaphylaxis

Shock (hypovolemic, cardiac, septic)

5.6.4.1.1.2

LESS COMMON CAUSES

Stenotic nares or choanal atresia

Neoplasia (nose, paranasal sinuses)

Nasal granuloma

Nasopharyngeal cicatrix

Tracheal stenosis, collapse, stricture

Tracheal rupture or perforation

Diaphragmatic hernia

Pneumothorax

Pulmonary edema

Smoke inhalation pneumonia

Pneumoconiosis interstitial pneumonia

Atrial septal defect with pulmonary hypertension

5.6.4.1.1.3

UNCOMMON CAUSES

Pulmonary lobar hypertrophy (foals)

Embryonal mediastinal cyst

Pulmonary tuberculosis, nocardiosis

Pneumocystis carinii pneumonia

Air embolism

Pulmonary neoplasia

Transposition of great vessels

Tricuspid atresia

Aortic, pulmonary artery rupture

Interruption of aortic arch

Common ventricle with separate pulmonary outflow chamber

Multiple cardiac anomalies

Methemoglobin reductase deficiency

Lactation tetany

Clostridial diseases

Malignant hyperthermia

5.6.4.1.1.4

TOXIC CAUSES

Sulfur, hydrogen sulfide

α-Naphthyl thiourea (ANTU)

Chlorinated hydrocarbon

Organophosphate, carbamate

Red maple *(Acer rubrum)*[*]

Redroot pigweed *(Amaranthus retroflexus)*[*]

Sudan grass *(Sorghum vulgare var sudanensis)*[*]

Mintweed *(Salvia reflexa)*[*]

Lamb's-quarters *(Chenopodium album)*[*]

Variegated thistle *(Silybum marianum)*[*]

Winged thistle *(Carduus tenuiflorus)*[*]

* Nitrate accumulator, which causes methemoglobinemia.

5.6.4.1.2

Box 5-17 Causes of Central Cyanosis in Ruminants

5.6.4.1.2.1

COMMON CAUSES

Bacterial pneumonia, pulmonary abscessation (*Mannheimia hemolytica, Arcanobacterium [Actinomyces] pyogenes, Pasteurella multocida, Corynebacterium pseudotuberculosis* [O, C], other bacteria)

Viral pneumonia (respiratory syncytial virus [B], ovine progressive pneumonia [O], caprine arthritis-encephalomyelitis [C], other viruses)

Parasitic pneumonia (*Dictyocaulus viviparus* [B], *Dictyocaulus filaria* [O, C])

Aspiration pneumonia

Acute bovine pulmonary edema and emphysema (B)

Pulmonary edema

Ventricular septal defect with pulmonary hypertension

Tetralogy of Fallot

Toxic methemoglobinemia

Anaphylaxis

Shock (hypovolemic, cardiac, septic)

Rumen bloat

5.6.4.1.2.2

LESS COMMON CAUSES

Obstruction of nasal passages or paranasal sinuses (neoplasm, granuloma, abscess, other)

Laryngeal abscess

Tracheal stenosis, collapse, stricture

Tracheal rupture, perforation

Diaphragmatic hernia

Prematurity, dysmaturity, immaturity

Inhalation pneumonia (smoke)

Pneumothorax

Hemothorax

Pulmonary contusion

Ventricular septal defect with pulmonic stenosis

Postparturient hemoglobinuria

Clostridial diseases (e.g., malignant edema, blackleg, tetanus)

Bluetongue (O)

Obstructive urolithiasis, ruptured urethra

5.6.4.1.2.3

UNCOMMON CAUSES

Pleural mesothelioma (B)

Water inhalation (drowning)

Pulmonary adenomatosis (O)

Transposition of great vessels

Double-outlet right ventricle

Common ventricle with separate pulmonary outflow chamber

Acute anthrax

White liver disease (exotic) (O)

Sweating sickness (exotic) (B, O)

5.6.4.1.2.4

TOXIC CAUSES

Strychnine

Arsenic

Metaldehyde

Hydrogen sulfide

Organochlorine, chlorinated hydrocarbon

Organophosphate, carbamate

Acute selenium toxicosis

Nitrate, nitrite

Perennial broomweed *(Gutierrezia microcephala)*

Oleander *(Nerium oleander)*

Whitehead *(Sphenosciadium capitellatum)*

Milkweed (*Asclepias* species) (O)

Rhododendron (*Andromeda* species)

Fireweed *(Kochia scoparia)*

Canary grass (*Phalaris* species)

Kikuyu poisoning (exotic) (B, O)

Albizia poisoning (exotic) (B, O)

Euphorbia, *Sarcostemma* poisoning (exotic) (B, O)

Acacia poisoning (exotic) (B, O)

Wild onion *(Allium validum)** [O]

Variegated thistle *(Silybum marianum)**

Redroot pigweed *(Amaranthus retroflexus)*

Sudan grass *(Sorghum vulgare var sudanensis)**

Winged thistle *(Carduus tenuiflorus)**

Mintweed *(Salvia reflexa)**

Lamb's-quarters *(Chenopodium album)**

Many pasture grasses fed during optimum growth conditions*

Locoweeds (*Astragalus* species, *Oxytropis* species)*

B, Bovine; *C*, caprine; *O*, Ovine.

* Netrate accumulator, which causes methemoglobinemia.

5.6.4.2

IMPAIRED DIFFUSION

Impaired diffusion, a second cause of hypoxemia, results from an increase in the blood-gas barrier. Equilibrium between alveolar oxygen and pulmonary blood oxygen is not reached because of the increased barriers through which oxygen must pass to reach hemoglobin. Because carbon dioxide diffuses more readily than oxygen, the $PaCO_2$ usually is not increased in conditions that cause impaired diffusion. In fact, the $PaCO_2$ may actually be reduced because of hyperventilation stimulated by hypoxemia. Conditions that may result in impaired diffusion are pneumonia, pulmonary edema, atelectasis, pulmonary contusions, and pulmonary neoplasms.

5.6.4.3 VENTILATION-PERFUSION MISMATCH

Ventilation-perfusion mismatch occurs eventually in all generalized pulmonary diseases and is the predominant mechanism by which hypoxemia develops in respiratory conditions. Overall gas exchange is impaired by uneven ventilation and blood flow. Lung areas that are overperfused in relation to ventilation (low ventilation/perfusion ratio) contribute disproportionate amounts of blood with a low Pa_{O_2} to the systemic circulation. Examples of respiratory diseases that can result in a low ventilation/perfusion ratio include bronchitis, bronchoconstriction, airway closure, pulmonary atelectasis or consolidation, and local restriction of lung movement. In the case of pulmonary embolization or decreased pulmonary arterial pressure, ventilation may exceed perfusion (high ventilation/perfusion ratio) and result in pathologic dead space. Pulmonary mechanisms can partly compensate for ventilation-perfusion inequalities. Alveolar hypoxia may lead to reflex pulmonary arterial constriction, which redirects blood flow to alveoli that are adequately ventilated. Airway hypocapnia can stimulate bronchoconstriction, resulting in redirection of airflow to better-perfused alveoli.

70

71

5.6.4.4 SHUNTING

Shunting is defined as any mechanism by which blood that has not passed through ventilated areas of the lung is added to arteries of the systemic circulation. The term *venous admixture* is used to describe venous blood that passes through the lungs without being properly oxygenated. Animals with venous admixture often hyperventilate and thus have normocapnia or hypocapnia in association with hypoxemia. The most common cause of shunting is congenital heart disease, which allows unoxygenated blood from the right heart to pass directly into the left heart without passing through the pulmonary circulation. Intrapulmonary anatomic shunts can result from pulmonary artery to pulmonary venous fistulas or severe lung lobe consolidation, in which a large part of the lung is ventilated but not perfused. Cyanosis or hypoxemia unresponsive to oxygen therapy suggests the presence of such congenital cardiac anomalies or intrapulmonary shunts.[84] Examples of the more common cyanotic congenital cardiac defects are tetralogy of Fallot, truncus arteriosus, transposition of the great arteries, tricuspid atresia, and hypoplastic left heart syndrome.[82,84] Aside from congenital defects, reversion to fetal circulation should be considered in any critically ill neonatal animal with hypoxemia that is unresponsive to oxygen insufflation.[84]

5.6.5 Approach to Diagnosis of Cyanosis

5.6.5.1 HISTORY

The history should include questions about the duration of the cyanosis (e.g., cyanosis that has been present since birth or an early age may indicate congenital heart disease with right-to-left shunting); possible exposure to toxic plants or chemicals that may result in production of abnormal types of hemoglobin; evidence of an abnormal respiratory pattern (respiratory distress, inspiratory stridor, cough); and signs of episodic weakness or syncope that may be consistent with congenital cardiac anomalies or severe upper airway obstruction (e.g., tracheal collapse or severe laryngeal edema associated with necrotic laryngitis in calves).

5.6.5.2

PHYSICAL EXAMINATION

The physical examination should include *inspection* to detect abnormalities in the respiratory pattern (e.g., tachypnea, respiratory distress, or stridor). Careful *auscultation* of the larynx, trachea, and lungs is also imperative. A rebreathing bag (8-L capacity for adult horses and cattle, 1- to 2-L capacity for calves, foals, and small ruminants) causes a temporary buildup of CO_2, stimulates the respiratory center, and prompts deep breaths when the animal is again allowed to inspire room air. Loud breath sounds, pulmonary crackles and wheezes, or pleural friction rubs may suggest that cyanosis is associated with a pathologic respiratory condition. Loud cardiac murmurs accompanied by precordial thrills point to congenital heart disease as the cause of cyanosis.

Palpation and *percussion* of the chest are also important examination procedures in an animal with cyanosis. Chest palpation may reveal pleural friction rubs or the pain and crepitus associated with rib fractures. Increased resonance on percussion may indicate pneumothorax, whereas decreased resonance suggests pulmonary congestion or consolidation, pleural effusion, or a space-occupying lesion in the thorax.

5.6.5.3

ENDOSCOPIC EXAMINATION

An endoscopic examination should be performed if upper airway obstruction or malformation is suspected (see Cough, p. 42; Nasal Discharge, p. 50; and Respiratory Distress, p. 60).

5.6.5.4

RADIOGRAPHIC EXAMINATION

Radiographs of the upper respiratory tract and thorax can be used to further characterize a pathologic respiratory condition. Abnormalities that may be detected include space-occupying lesions in the oropharynx, nasopharynx, or larynx; tracheal compression or collapse; enlargement or distortion of the cardiac silhouette; pulmonary consolidation; pneumothorax; pleural effusion; and pulmonary abscessation.

5.6.5.5

ULTRASOUND EXAMINATION

Ultrasound examination of the chest and heart is indicated to characterize cardiac anomalies and to detect the presence and determine the extent of pleural effusion, pulmonary consolidation, and pulmonary abscessation.

5.6.5.6

ARTERIAL BLOOD GAS ANALYSIS

Arterial blood gas analysis is indicated to determine O_2 and CO_2 tension (see Respiratory Distress, p. 60).

5.6.5.7

COMPLETE BLOOD COUNT

A complete blood count should be performed to determine if polycythemia or inflammatory leukogram is present. Polycythemia may develop secondary to chronic hypoxemia associated with long-standing pulmonary disease or right-to-left shunting. An inflammatory leukogram would be consistent with a diagnosis of bacterial or aspiration pneumonia or other inflammatory respiratory condition.

5.6.5.8 HEPARINIZED BLOOD

A sample of heparinized blood should be shaken gently in the air for 15 minutes. Reduced hemoglobin (cardiovascular or respiratory disease) turns red on exposure to air, whereas methemoglobin remains chocolate brown after shaking.

5.6.5.9 SPECTROSCOPIC EXAMINATION

A spectroscopic examination should be performed to determine if methemoglobin is present. Methemoglobin is stable in refrigerated heparinized blood for only a few hours. To preserve methemoglobin, one part of blood can be mixed with 20 parts of phosphate buffer (pH 6.6) or diluted 1:20 in distilled water. These diluted samples can be refrigerated or frozen until they are analyzed.

5.7 ABNORMAL RESPIRATORY NOISE (STRIDOR)

5.7.1 Definition

Stridor is an abnormal, intense respiratory sound (wheeze) that is audible without the use of a stethoscope. The sound usually is generated in the upper airway and is most often heard during inspiration.

5.7.2 Pathophysiology

The extrathoracic airway of the horse consists of segments that are relatively rigid (e.g., the nasal fossa and extrathoracic trachea) and others (e.g., the nostrils, soft palate, and larynx) that not only are elastic but also have valvelike actions that are further capable of modifying the cross-sectional area and therefore resistance to airflow.[85,86] Pressures in the extrathoracic airways are subatmospheric during inspiration,[85–87] which causes the less rigidly supported parts of the upper airway to narrow (dynamic narrowing or collapse) during inspiration.[85–90] A major function of the upper airway muscles and other supporting structures is to prevent this dynamic collapse during periods of high inspiratory gas flow.[85] Disease in these structures or a more rostral obstructing lesion that causes a greater negative pressure during inspiration may make them incapable of resisting axial displacement.[85,87] The increased resistance to flow induced by static or dynamic obstructions increases the driving pressure and therefore the work needed to move a given volume of air.[86]

71

72

Approximately 80% of the total airway resistance to gas flow at rest and during exercise is located in the upper airway rostral to the thoracic inlet.[87] Nasal resistance, most of which is caused by resistance just within the external nares, comprises more than 50% of the total upper airway resistance in the horse.[88,89] In most species, including ruminants, this resistance can be bypassed by mouth breathing to accommodate the high airflow rates that accompany strenuous exercise. The horse, in contrast, is limited to nasal breathing even during exercise,[87–89,91] because the larynx is firmly maintained in an intranarial position by the tight seal formed around it by the muscular palatopharyngeal ring (intrapharyngeal osteum) except during swallowing.[91,92] Therefore mechanisms other than mouth breathing are needed to reduce the energy cost of breathing in the horse.[85,88,91] These mechanisms include dilation of the distensible external nares by actively pulling the alar folds laterally,

vasoconstriction in the erectile nasal vascular tissues to reduce congestion in the nasal mucosa, straightening of the respiratory tract, and dilation of the larynx by abduction of the vocal folds.[85–88,90,91,93,94]

The horse is capable of generating very high respiratory rates during fast exercise. This is accomplished at the canter and gallop, but not at the trot, by locking respiration to locomotion so that the horse takes one breath for each stride.[92,95–97] Exhalation occurs each time the lead forelimb strikes the ground.[91,92,95] The horse can swallow during fast galloping exercise; the entire process is completed in exactly a two-stride sequence.[92,98]

At all levels of the respiratory tract, respiratory sounds are thought to result from vibrations in tissue and sudden changes in the pressure of gas moving in the airway lumen.[87,92] Airflow in the normal respiratory tract at rest occurs in a laminar fashion (i.e., the air closest to the wall of the airway is almost stationary, whereas succeeding layers toward the center of the lumen move progressively more rapidly).[92] Respiration in normal horses and in ruminants at rest does not generate easily audible sounds.

High rates of gas flow and airway narrowing increase both the tendency for dynamic collapse and the degree of turbulence and genesis of sounds. Very high peak flow rates of 125ml/sec/kg have been reported in galloping horses.[97] During exercise significant sound frequencies are generated and can be detected using sound spectrography or radiostethoscopes, although most of these sounds are of frequencies and amplitudes not detectable by the human ear.[99,100] Deformities in the wall and masses in the lumen of the airway cause airway narrowing and further disturbances in laminar flow, resulting in more severe turbulence and sudden changes in the pressure of moving gas, which may generate audible sounds.[92] High airflow rates are necessary to induce most audible stridors; therefore examination of the horse at exercise is an essential part of the physical examination.[91,92]

Stridor is best heard during inspiration in most cases because the usual source of origin, the upper airway, is subject to dynamic narrowing during the inspiratory phase of the respiratory cycle.[85,88,89] In particular, nonfixed obstructions, such as the paretic vocal folds of horses with idiopathic laryngeal hemiplegia (ILH), cause obstruction to airflow and turbulence only when dynamically drawn into the airway by the high inspiratory airflow rates that accompany fast exercise. Other obstructions such as arytenoid chondritis are fixed and obstruct airflow during both inspiration and expiration, which frequently results in audible stridor during both phases of respiration.

The pharynx is the site of greatest airway angulation as a result of flexion of the atlantooccipital joint. At rest the horse's head is usually held at about 50 degrees to the horizontal plane.[92] At the gallop the horse extends its head and neck and thus straightens the pharyngeal airway.[92] This maneuver also stretches and straightens the trachea, making it less compliant and less subject to dynamic narrowing during inspiration.[88] When ridden at a collected canter, the horse is forced to flex its poll so that its face is nearly vertical, thereby increasing the angulation of the pharyngeal airway and the obstruction to gas flow at this point.[92] Therefore abnormal respiratory sounds originating in the pharyngeal region are often more easily heard when the horse is ridden at a collected canter than when it is exercised at a full, extended gallop.[91,92]

Because food animals are not normally expected to perform fast exercise, signs of stridor are usually present at rest when the animals are presented to veterinarians for examination. Stridor in resting animals usually indicates moderate to severe upper airway obstruction of a fixed nature. In ruminants the epiglottis is relatively short and blunt, and the palatopharyngeal ring allows the laryngopalatal dislocation necessary for mouth breathing. In conditions that give rise to respiratory distress and mouth breathing, the turbulence produced is often sufficient to

induce abnormal (grunting) expiratory sounds, which may be classified as expiratory stridor. The external nares of cattle are much less compliant than those of sheep, goats, and horses, which prevents dynamic collapse during inspiration; thus conditions such as paresis of the nares that cause stridor in sheep, goats, and horses do not cause stridor in cattle (Boxes 5-18 and 5-19).

5.7.3 ## Approach to Diagnosis of Stridor

5.7.3.1 ### HISTORY

The procedure for taking a history should follow that used in the evaluation of cough and nasal discharge (see Cough, p. 42, and Nasal Discharge, p. 50). The history should also include the duration of ownership; time of onset of the clinical signs of stridor; progression of clinical signs; presence or absence of the noise at rest; relation of noise to fitness; relation of noise to speed, duration, and direction of work; relation of noise to head position during work; association of noise with poor performance or exercise intolerance; and other signs of respiratory tract, oropharyngeal, or neurologic disease (e.g., nasal discharge, cough, dysphagia, or retropharyngeal swelling).

5.7.3.2 ### PHYSICAL EXAMINATION

A physical examination of the entire respiratory tract at rest should be performed as described for cough (see p. 42) and respiratory distress (see p. 60). In addition, the presence or absence of stridor at rest should be ascertained by listening at the nostrils, and digital pressure should be applied to the retropharyngeal region and to the larynx during palpation of these areas to evaluate whether stridor or pain (or both) can be easily induced or exacerbated. The dorsal surface of the larynx should be palpated with the fingertips with the horse relaxed and its head and neck in an extended position. This permits comparison of the prominence of the muscular process of the arytenoid cartilages and the thickness of the cricoarytenoideus dorsalis (CAD) muscle, both of which are affected in horses with atrophy of the CAD in association with ILH. Air turbulence, flattening, swelling, and pain should be assessed during palpation of the extrathoracic airway. The larynx, trachea, and lungs should be carefully *auscultated*, and the chest should be *percussed*. A thorough oral examination should be completed, particularly in ruminants; in cattle this should include palpation of the base of the tongue, the oropharynx, and, if possible, the larynx through the oral cavity.

72

73

5.7.3.2.1 #### Box 5-18 Causes of Stridor in Horses

5.7.3.2.1.1 ##### COMMON CAUSES

Idiopathic laryngeal hemiplegia (ILH, roaring)

Dorsal displacement of the soft palate (laryngopalatal dislocation)

Epiglottic entrapment

Retropharyngeal abscess

Strangles (*Streptococcus equi* infection)

Guttural pouch empyema

Chronic pharyngeal lymphoid hyperplasia

Arytenoid chondritis

Guttural pouch mycosis

Laxity of the alar cartilage

5.7.3.2.1.2

LESS COMMON CAUSES

Arytenoid chondroma, chondropathy

Pharyngeal paresis

Botulism, shaker foal

Dynamic collapse of the pharynx

Subepiglottal, pharyngeal cyst

Subepiglottal abscess

Epiglottal retroversion

Guttural pouch tympany

Guttural pouch neoplasia

Rostral displacement of the palatopharyngeal arch

Nasal fungal infection (e.g., aspergillosis, rhinophycomycosis)

Nasal polyp

Nasal foreign body

Nasal trauma

Nasal tumor

Nasopharyngeal cicatrix

Progressive ethmoidal hematoma

Sinusitis (sinus empyema)

Sinus cyst

Sinus tumor

Atheroma

Laryngeal trauma

Tracheal collapse (scabbard trachea)

Tracheal stricture, stenosis

Tracheal chondroma

Tracheal rupture, perforation

Stenotic nares

Laryngeal edema

Purpura hemorrhagica

Anaphylaxis or acute drug reaction

Chronic lead poisoning

Choanal (posterior nares) atresia, hypoplasia (foals)

Fracture of laryngeal cartilages

Laryngeal granuloma, scar tissue

Equine influenza

Exercise-induced pulmonary hemorrhage (EIPH)

Jugular thrombosis

Hyperkalemic periodic paralysis (HYPP)

5.7.3.2.1.3

UNCOMMON CAUSES

Amyloidosis (cutaneous, nasal)

Lymphosarcoma, lymphoma

Bee or wasp sting

Snakebite

Thyroid adenoma, adenocarcinoma

Vesicular stomatitis

Retrobulbar neoplasia

Dystrophic myodegeneration (white muscle disease)

Neoplasia (oral, mandibular, maxillary, laryngeal, pharyngeal, tracheal)

Coccidioidomycosis

Inhalation pneumonia, smoke inhalation

Burns (thermal, chemical)

Congestive cardiac failure

Cutaneous habronemiasis

Unilateral ventral displacement of the roof of the nasopharynx

Epiglottiditis

Hyoid bone injuries

Fungal granuloma, maduromycosis, rhinosporidiosis, mycetoma, cryptococcal rhinitis, equine nasal granuloma

Goiter

Hypertrophic ossification of the laryngeal cartilages

Abnormalities of the nasal septum

Intramural esophageal cyst

Foreign body (nasal, pharyngeal, laryngeal, tracheal, bronchial)

Hyperparathyroidism

Phycomycosis, pythiosis

Anaerobic abscesses (e.g., *Clostridium perfringens*)

Besnoitiosis, globidiosis (exotic)

Glanders (exotic)

5.7.3.2.1.4

TOXIC CAUSES

Organophosphate-induced laryngeal paralysis

Lead-induced laryngeal paresis

Reserpine

5.7.3.3

FIELD EXERCISE TESTING[92]

In performance horses most examinations are carried out because the horse makes a noise only when worked, because of exercise intolerance or poor performance, or as part of a prepurchase examination. Unless a high-speed treadmill is available, the exercise testing should be completed under saddle with a competent rider, preferably with an intensity of work that matches the horse's normal activity.[87,91] It is less satisfactory but often necessary to work the horse on a lunge line, in which case it should be lunged in both directions.[91]

The horse should be worked in a circle about 30 yards in diameter so that it passes close to the observer on each circuit.[92] The observer should first identify the expiratory sound by its association with locomotion and then try to fit abnormal sounds into this base rhythm. At fast speed respiration is very rapid; thus the observer should not stand too far away from the horse because the slow speed at which sound is transmitted confuses interpretation of whether the sound is inspiratory or expiratory.[92,98] In cold weather the visibility of exhaled breath aids interpretation. It is important to ride the horse in both directions because an abnormal sound is frequently heard more clearly when the horse is exercising in one direction than in the other.[91] If the presence or character of a respiratory noise remains in doubt after the horse has been exercised in a circle at a collected canter, the horse should be galloped until it is blowing hard then ridden past the observer at a fast gallop.[91]

A satisfactory exercise test should include at least 5 minutes of work at the canter, after which the horse should immediately be brought over to the observer so that the character and sequence of abnormal sounds that persist can be determined. All horses that have been worked adequately make a loud expiratory blowing sound at this time. Turbulence of airflow in the larynx may be audible with a stethoscope.[92] Inducing adduction of the vocal fold, particularly on the right side, by application of gentle pressure in a rostromedial direction to the muscular process of the arytenoid cartilage often accentuates an inspiratory noise in horses with laryngeal hemiplegia. Noises originating from unilateral lesions in the nasal passages are easily localized because the sound can be eliminated by alternately blocking off airflow through each nostril with the hand. Temporary occlusion of both nostrils simultaneously may provoke laryngopalatal dislocation and a loud gurgling sound in a susceptible horse.[91,92] The presence of nasal discharge or blood at the nostrils should be noted, and the time required for the heart and respiratory rates to return to preexercise values should be interpreted in light of the severity of the exercise test.[91]

5.7.3.3.1

Box 5-19 Causes of Stridor in Ruminants

5.7.3.3.1.1

COMMON CAUSES

Necrotic laryngitis (calf diphtheria) (B, O)

Abscess (pharyngeal, laryngeal, retropharyngeal, oral)

Nose bots *(Oestrus ovis)* (C, O)

Caseous lymphadenitis *(Corynebacterium pseudotuberculosis)* (C, O)

Actinobacillosis (wooden tongue, nasal actinobacillosis)

Nasal adenocarcinoma, adenoma, adenopapilloma, polyp (C, O)

Trauma (oral, nasal, pharyngeal, laryngeal, tracheal)

Anaphylaxis or drug reaction

Sinusitis

Foreign body (nasal, oral, pharyngeal, laryngeal, tracheal, bronchial)

5.7.3.4

INTERPRETATION OF ABNORMAL SOUNDS

A normal horse makes no audible respiratory sound at rest and when exercised at a canter or slow gallop makes only a blowing expiratory sound.[87,91,92] In unfit horses, particularly overweight ones, an inspiratory sound is

also frequently audible. This sound can be quite loud, and it may be difficult to differentiate from sounds caused by abnormalities of the respiratory tract.[90,91] Thus evaluation of the horse's “wind” is best carried out when the horse is in fit condition for its intended use. It takes at least 1month for an older horse that has been turned out to pasture to regain a satisfactory level of fitness to perform a meaningful wind examination. Many normal horses produce a harsh expiratory “high blowing sound” of variable pitch, which results from resonance in the cavity of the false nostril during expiration.[91,92,98] If the source of the stridor remains in doubt, temporary suturing of the alar fold dorsal to the nostril can help localize noises suspected of being caused by vibration of the alar fold.

Horses with ILH make a rather characteristic biphasic sound, the inspiratory sound occurring between successive expiratory sounds. The pitch of the sound can vary from a whistle to a deep roar, the lower-pitched note giving rise to the so-called “sawing wood” sounds.[92] Sonographic and spectrographic analysis of the sounds produced by “roarers” indicates that the range of sound frequencies generated by these horses is the same as that produced by normal horses.[99,100] However, horses that make an audible whistle generate an intense band of frequencies centered on 1.9kHz that are thought to result from amplification by the still-patent lateral ventricle of the frequency generated by vibration of the incompletely abducted left vocal fold.[100] In a normal horse the left vocal fold is fully abducted, and the cavity of the lateral ventricle is thus obliterated during strenuous exercise.[94]

The sounds generated by horses with laryngeal chondritis, severe proliferative pharyngeal lymphoid hyperplasia, epiglottic entrapment, and tracheal stenosis can be very similar to those caused by ILH.[91,92] Laryngopalatal dislocation (dorsal displacement of the soft palate) gives rise to a transient, vibrant, gurgling sound.[89,91,92] In many instances a severe exercise test is required to induce this condition; thus this sound may be heard only during a race.[87,91,92] It is thought that the condition may occur when pharyngeal stimulation causes swallowing during fast exercise.[92] Instead of the horse completing the process and regaining the laryngopalatal seal consistent with the respiratory position of the larynx in the nasopharynx, the tip of the epiglottis disengages from the rostroventral aspect of palatopharyngeal ring (caudal free border of the soft palate), resulting in the entire epiglottis slipping ventral to the soft palate. At the subsequent inspiration the palatopharyngeal arch tends to be drawn into the rima glottis, and at expiration it is driven toward the roof of the pharynx by the air stream. The palatopharyngeal arch acts as an airway obstruction, and the tissue vibration and resulting turbulence generate a sound of varying pitch and intensity, often described as gurgling followed by swallowing.[92] The horse often slows suddenly or stops when this event occurs, and the jockey often reports that the horse stopped after “choking” or “swallowing its tongue.” If repeated swallowing is successful in relocating the normal laryngopalatal respiratory arrangement, the horse often continues to race after slowing or stopping.[70]

74

75

Gross obstruction of the airway by pressure from pus-filled guttural pouches, retropharyngeal abscesses, large subepiglottal cysts or abscesses, or large proliferative lesions (e.g., laryngeal tumors) produces loud, stertorous breathing (snoring) often heard at rest and readily so with exercise; both inspiratory and expiratory sounds are clearly audible.[92]

In a normal horse the pattern of respiratory sounds is regular and synchronized with the pace of the exercise. Laryngeal irritation caused by exudate from the upper or lower airway, pharyngeal lymphoid hyperplasia, or other inflammatory or space-occupying conditions causes the horse to swallow more frequently during exercise, which generates an irregular pattern of respiratory sounds characterized at the canter and gallop by a respiratory cycle of double the normal length.[92,98]

Interpretation of stridor in yearlings presented for sale is difficult because these animals are rarely fit and it is usually possible to exercise them only at a canter on a lunge line. It has been shown that resentment of restraint under such circumstances can significantly alter the linking of locomotion and respiration, which complicates recognition of the respiratory phasing of noise production.[94] In addition, there is not always a close correlation between noise production, endoscopically visible abnormalities, and signs of exercise intolerance even in fit adult horses.[87,91]

5.7.3.5

ENDOSCOPIC EXAMINATION

Endoscopic examination of the upper airway is the most useful diagnostic procedure for investigating stridor. The examination should be performed at rest before exercise and again immediately after exercise or, if possible, during exercise on a high-speed treadmill. Endoscopic examination immediately after cessation of exercise is less satisfactory than endoscopy during treadmill exercise because dynamic collapse of the rima glottis terminates rapidly on cessation of exercise. Because sedatives and tranquilizers may alter the tone and function of the muscles supporting laryngeal and pharyngeal anatomy, endoscopic examination should be performed without chemical restraint whenever possible.[87] The nasal passages, conchae (turbinates) (including the ethmoidal concha), nasal septum, pharynx, larynx, and trachea should be examined through both nostrils so that the presence, nature, and source of exudates and the presence of anatomic or functional abnormalities or mass lesions can be determined. If problems are suspected in the guttural pouches, the interior of these structures should be examined for exudate, proliferative lesions, or arterial aneurysms by advancing the endoscope through the pharyngeal openings. Because the larynx is viewed slightly obliquely when examined from the left or the right ventral meatus, an apparently asymmetric larynx should be viewed through both nostrils.[87,91]

Interpretation of the findings of the endoscopic examination of the pharynx and larynx is by no means straightforward. The results can be influenced by the day the examination was done, the use of sedation, the side through which the endoscope was passed, and the observer's interpretation.[101] The appearance of laryngeal symmetry or asymmetry in resting horses varies considerably and therefore is of limited clinical usefulness unless complete hemiparalysis is present. Many horses have asynchronous or asymmetric laryngeal movement at rest but not during exercise, whereas other horses have a normal-appearing larynx at rest but suffer dynamic collapse during exercise. Interpretation of findings is improved by use of an objective grading system, which includes assessment of the ratio of the areas of the left and right half of the rima glottis and by correlating findings at rest with those observed on video endoscopy performed during maximal exercise.[101] For evaluation of the larynx at rest, full abduction of the vocal folds should be induced by exercise or by temporary occlusion of the nostrils.[91] Contralateral adductory laryngeal move-ment should be stimulated by slapping the horse just behind the withers (slap test).[102] To induce the horse to swallow, the tip of the epiglottis should be touched with the endoscope, or water should be flushed through the endoscope. These maneuvers help to establish whether movement of the arytenoid cartilages is synchronous and symmetric and increase the predictive value of endoscopic observations, allowing laryngeal function to be graded as follows.[101]

- *Grade 1:* Synchronous, full adduction and abduction of the left and right arytenoid cartilages (considered normal).
- *Grade 2:* Asynchronous movement such as hesitation, fluttering, or adductor weakness of the left arytenoid cartilage during inspiration, expiration, or both, but full abduction of the left arytenoid

cartilage, inducible by nasal occlusion or swallowing. Grade 2 findings are considered a normal variation and are not usually associated with dynamic airway collapse during exercise.

- *Grade 3:* Asynchronous movement of the left arytenoid cartilage during inspiration, expiration, or both, but full abduction is not inducible by nasal occlusion or induction of swallowing. The true functional significance of grade 3 findings can be determined only by performing endoscopic examination during maximal exercise on a high-speed treadmill, a procedure that has led to subclassification of grade 3 findings.[103] Some grade 3 horses *(grade 3A)* are able to achieve full abduction during exercise, whereas others maintain a partly abducted position similar to the resting position *(grade 3B)* or experience dynamic collapse *(grade 3C)*.[103]

- *Grade 4:* Marked asymmetry of the larynx at rest and no substantial movement of the left arytenoid cartilage during any phase of respiration. These horses have complete left laryngeal hemiplegia, are true "roarers," and consistently experience dynamic collapse on inspiration during strenuous exercise.[101]

Performing an endoscopic examination during maximal exercise on a high-speed treadmill makes it possible for a stationary observer to gain a good dynamic appreciation of the significance of upper airway abnormalities (i.e., dynamic endoscopy)[103–107] (see Exercise Intolerance and Poor Performance in Horses, p. 76). Dynamic changes in airway lumen diameter occur quickly during treadmill endoscopy and may be difficult to visualize; therefore the endoscopic examination should be videotaped for later playback in slow motion and freeze-frame.[107] It is important to exercise horses maximally and to exhaustion (inability to keep up with the treadmill), because some abnormalities are apparent only at maximal exercise toward the end of a race when pharyngeal or laryngeal muscles become fatigued and are no longer able to resist the transmural pressure gradient, which tends to induce dynamic collapse of the upper airway during inspiration.[103–107] Endoscopic identification of an upper respiratory tract abnormality in a resting horse does not necessarily mean that it is inducing a problem during exercise, and, conversely, the absence of an upper respiratory tract abnormality at rest does not rule out the possibility of intermittent airway obstruction during strenuous exercise. For example, dorsal displacement of the soft palate, epiglottic entrapment, dorsal displacement of the epiglottis, dynamic collapse of the left arytenoid cartilage or vocal fold (or both), and unilateral or bilateral ventral displacement of the roof of the pharynx (dynamic pharyngeal collapse) have been observed during treadmill exercise in horses with an endoscopically normal upper airway at rest.[103–107]

75
76

5.7.3.6

RADIOGRAPHIC EXAMINATION

Radiographic examination of the nasal passages, paranasal sinuses, pharynx, retropharyngeal area (including guttural pouches), larynx, and proximal trachea is indicated to confirm anatomic or functional problems or space-occupying lesions not definitively diagnosed by clinical examination and endoscopy (see Nasal Discharge, p. 50 and Respiratory Distress, p. 60). Radiography is particularly useful for visualizing subepiglottic masses such as cysts or abscesses and for evaluating the epiglottis of the horse when it is obscured from endoscopic view by dorsal displacement of the soft palate or other space-occupying lesions. An accurate assessment of epiglottic length can also be made from standardized true lateral radiographs of the larynx by measuring the distance from the body of the thyroid cartilage to the tip of the epiglottis (thyroepiglottic length).[108] The mean ± SD (standard deviation) thyroepiglottic length in normal thoroughbred horses is reported to be 8.76 ± 0.44cm.[108] Significantly shortened thyroepiglottic lengths have been recorded in thoroughbred horses with dorsal displacement of the soft palate (laryngopalatal dislocation) and in those with entrapment of the

epiglottis in the aryepiglottic folds.[108] Tracheal diseases such as chondroma or dynamic collapse may be visualized on radiographs of the trachea, particularly those made during the inspiratory phase.

5.7.3.7 ULTRASOUND EXAMINATION

Ultrasound examination of externally visible lesions such as possible retropharyngeal abscesses that may be impinging on the airway helps to characterize lesions and assist in the collection of samples by aspiration or biopsy.

5.7.3.8 BIOPSY

Biopsy and histologic evaluation of samples are indicated to diagnose certain mass lesions such as neoplasms, cysts, polyps, fungal granulomas, or foreign body granulomas in or surrounding the airway. Masses in the airway can be biopsied through the biopsy channel of fiberoptic or video endoscopes, but these samples inevitably are small. Larger samples can be collected from lesions in the nares, nasal diverticulum, and nasal passages using uterine biopsy forceps, laparoscopy forceps, or curettes. Hemorrhage usually accompanies such procedures. Biopsies can also be collected at the time of exploratory or corrective surgery from lesions in the nasal passages, pharynx, larynx, and guttural pouches. Lesions such as habronemiasis involving the external nares and lesions in other accessible areas such as the parotid salivary gland can be biopsied percutaneously using Tru-Cut or similar instruments.

5.7.3.9 ASPIRATION

Aspiration, performed either blindly or with the assistance of ultrasound, followed by cytologic examination and culture of aspirated material is useful in the evaluation of masses such as retropharyngeal abscesses that are causing stridor by impinging on the upper airway.

5.7.3.10 SWABBING OR SCRAPING

Nasal or nasopharyngeal swabbing or scraping followed by direct cytologic examination and culture is indicated for confirmation of nasal fungal infection and bacterial infections of the upper airway (e.g., strangles).

5.7.3.11 COMPLETE BLOOD COUNT

A complete blood count, including fibrinogen concentration, can be useful in evaluating patients suspected of having a primary or secondary inflammatory condition or conditions such as ethmoidal hematoma and guttural pouch mycosis in which blood-loss anemia is likely to be a complicating problem.

5.7.3.12 ASPIRATION, LAVAGE, OR THORACOCENTESIS

Transtracheal aspiration, BAL, and/or thoracocentesis with cytologic examination and culture of collected samples are indicated in the evaluation of patients suspected of having disease of the lungs or pleura.

5.8 EXERCISE INTOLERANCE AND POOR PERFORMANCE IN HORSES

Stephanie J. Valberg

W. David Wilson

The popularity of performance horses has broadened our perspective on health beyond the conventional diagnosis of health or disease in a horse at rest. Sports medicine defines equine health as the optimum function of all body systems during the expected level of performance. Because many body systems function at only a small fraction of their maximum capacity in a resting athlete, a clearer understanding of exercise responses in the horse and new methods of evaluating horses during exercise are needed.

5.8.1 Exercise Responses

As horses accelerate during exercise, motor units within active muscles fire in a coordinated fashion to produce the power necessary to drive the animal forward. Initially, slow-twitch type 1 muscle fibers are recruited, followed at increasing speed by recruitment of oxidative fast-twitch type 2A fibers and finally the fastest and most powerful muscle fibers, type 2B (also called 2X). The increased demand for adenosine triphosphate (ATP) to support muscle contractions during exercise can be met initially by small intracellular stores of creatine phosphate, but within seconds oxidative or glycolytic metabolism (or both) is activated. At submaximal speeds the major factors contributing to fatigue are total depletion of fuel reserves (glycogen), fluid and electrolyte losses, and hyperthermia.[109] Training increases the oxidative and endurance capacity of skeletal muscle by increasing the volume of mitochondria and the capillary density surrounding muscle fibers.[110] This delays the onset of fatigue by increasing the availability and metabolism of plasma free fatty acids and glucose, thus sparing muscle glycogen. Training also fine-tunes the motor unit recruitment pattern to provide the most efficient and coordinated pattern of movement.

When a horse accelerates toward a maximum speed, a peak in the total amount of oxygen consumed is realized (Vo_{2max}). Additional energy to produce speeds beyond Vo_{2max} must be supplied by anaerobic glycolysis with lactic acidosis as a consequence. The term *anaerobic threshold* has been used to describe the speed at which this exponential rise in lactate begins to occur. Fatigue with maximum (fast) exercise occurs when muscle pH falls so low that glycolysis and excitation contraction coupling are inhibited and muscle ATP concentrations fall.[111,112] Muscle glycogen stores are not a limiting factor with maximum exercise. ??????[113] Training over time increases the mitochondrial volume and the ratio of type 2A to type 2B muscle fibers.[110,114] As a result, the onset of anaerobic metabolism is delayed until a higher speed is reached, and horses are able to maintain a higher speed over a given distance.

The cardiovascular system plays a central role in the oxygenation of blood by the lungs, in the delivery of oxygen and other energy substrates to exercising muscles, and in the removal of metabolic products from those muscles. Cardiac output increases with exercise in horses, largely as a function of an increase in heart rate.[115] As exercise begins, the heart rate quickly increases then reaches a steady state within minutes at a submaximal speed. With increasing exercise intensity the heart rate shows a linear relationship with speed up to a maximum rate of 210 to 230 beats/min. The mean systemic arterial pressure does not change with submaximal exercise but rises with maximum exercise. Mean pulmonary arterial pressures increase with speed as the heart rate increases, reaching remarkably high levels that are four times resting values.[116] The oxygen-carrying capacity of the blood also rises with increasing speed through splenic contraction and a more than 50% increase in blood hemoglobin.[117] The increase in blood viscosity that occurs with splenic contraction is believed to contribute to the increase in blood pressure with exercise. Among the adaptive cardiovascular responses to training are a lowered heart rate and

blood pressure at the same exercise intensity[118]; increased red cell volume[100]; and increased capillarization of muscle.[110]

After an initial abrupt rise the respiratory rate increa-ses linearly with the speed of trotting until, at a canter or gallop, respiration is linked to stride frequency on a 1:1 basis.[119,120] This leaves less time available for completing a respiratory cycle at faster speeds. To counter this, inspiratory and expiratory airflow velocities must increase to maintain or increase minute volume. As airflow rates increase, increased turbulence and an increased tendency for dynamic narrowing of the airways causes an increased resistance to flow and increases the work (energy cost) of breathing.[121,122] A finite maximum flow rate is eventually achieved, beyond which the expiratory muscles and the physical characteristics of the respiratory tract do not permit further increases in flow rate.[121] In addition, a maximum stride frequency is reached, restricting the maximum respiratory rate to 140 to 150 breaths/min.[119,120] It has been suggested that beyond the finite maximum flow rate, the animal is forced to hypoventilate, which may result in arterial hypoxemia during fast exercise.[123] The limitation placed on oxygen diffusion by blood hyperviscosity and the short transit time of blood through the pulmonary capillary bed at rapid heart rates also likely contribute to arterial hypoxemia.[124] The arterial hypoxemia and incomplete saturation of hemoglobin that occur during strenuous exercise do not necessarily limit delivery of oxygen to the tissues, however, because the decline in blood oxygen tension is offset by the increase in the total blood hemoglobin oxygen content resulting from splenic contraction. This fact and the horse's ability to sustain at least a sixfold increase in cardiac output between rest and the point of maximum oxygen uptake ($V_{O_{2max}}$)[125] are the major factors that contribute to the enormous aerobic capacity of the horse.

In contrast to the muscular and cardiovascular systems, the respiratory system shows little adaptation to training. Whether the apparent inability of the equine respiratory system either to adjust to training[126] or to compensate fully for the increased flow demands of heavy exercise limits athletic performance remains to be proven. However, it is likely that the maximally exercising horse is operating near the upper limit of ventilation and that even slight degrees of respiratory disease profoundly affect oxygen uptake and performance.[127] Any condition that causes increased resistance to airflow, decreased minute volume, decreased diffusion of gases, ventilation-perfusion mismatch, shunt, or increased oxygen cost of breathing constitutes a respiratory cause of exercise intolerance.

5.8.2 Approach to Diagnosis of Exercise Intolerance and Poor Performance

Top athletes arise from both a genetic background that emphasizes athletic ability and environmental influences that capitalize on this inherent potential. A coordinated, energy-efficient gait, muscular power and endurance, a large capacity for oxygen transport, and several intangible factors, such as the horse's mental toughness and competitive spirit and the rider's skill, all contribute to successful performance. *Poor performance* most often results from inadequate training, a lack of genetic potential, or both or from a congenital or acquired dysfunction of the locomotor, cardiovascular, or respiratory systems. The term *exercise intolerance* is often used to describe this inability to perform up to an expected or previously attained intensity of exercise.

5.8.2.1 HISTORY

An accurate history is a fundamental part of the evaluation of exercise intolerance and should include the age, breed, and use of the horse and the training and feeding programs. The onset (time and rapidity) of the problem, previous performance history, the activity level at which signs are observed, whether the horse performs well at

first then suffers tailing off of performance (no stamina) or whether performance is poor throughout the work period should be ascertained. If performance drops off during work, it should be established whether the drop-off is associated with the onset of other signs such as stridor. The presence of coughing, respiratory distress, stridor, excessive sweating associated with stress or exercise, or muscle stiffness should be noted. It should be ascertained whether the affected horse or in-contact horses have recently shown signs of respiratory disease, especially viral infections, and whether other horses are perceived to be performing poorly. It should be determined if the horse has shown lameness, gait abnormalities, or bitting problems. Any medications or other treatments that have been used and their effects should be noted.

In particular, it is important from the history to distinguish between horses that have never been able to perform satisfactorily and horses that suddenly or gradually show a reduction in the level of performance after a background of satisfactory performance. The first scenario suggests a lack of genetic potential, congenital abnormalities, or inadequate training. Some horses do not have the genetic background to perform the expected work (e.g., racing quarter horses rarely make good endurance horses, and thoroughbreds from sprinting families rarely excel at distances of more than 1¼ miles).

5.8.2.2

CLINICAL EXAMINATION

Overt clinical diseases that cause exercise intolerance at moderate speeds usually can be diagnosed with a good history, physical examination, and selected ancillary diagnostic techniques. The diagnostic procedures and specific diseases that can be identified at rest are detailed in subsequent chapters in this book (particularly Chapters 30, 31, 37, 38, and 42). Problems that are subclinical at rest provide a greater diagnostic challenge. When testing procedures at rest fail to identify the cause of exercise intolerance, various types of ancillary diagnostic procedures including exercise tests may be used to further define the problem. Because the respiratory, cardiovascular, musculoskeletal, and hematopoietic systems are all important for competitive performance and because diseases in these systems are the most likely causes of exercise intolerance, these systems should receive particular attention in the detailed clinical examination of the horse at rest.

77

78

5.8.2.3

HEMATOLOGIC ASSESSMENT

Hematologic tests have historically been popular in the evaluation of fitness and performance because they are easy to perform and because of the important role of hemoglobin in oxygen transport.[128,129] Routine hematologic evaluation may be useful in monitoring the general health status and perhaps fitness of horses if the conditions of collection, particularly in relation to time of day and exercise, can be carefully controlled and if attention is paid to horses that become excited before or during sample collection.

Anemia can result in a decreased oxygen-carrying capacity during exercise. Veterinarians traditionally have regarded resting hematocrits below 35% as abnormal and likely to cause suboptimal racing performance, but values lower than this have been found in normal thoroughbred racehorses.[130] Endurance horses and eventing horses usually have resting hematocrit values that are lower than those of racehorses.[130] However, the fact that a significant proportion of equine red blood cells and hemoglobin are contained in the splenic reserve makes interpretation of resting values for these parameters difficult (inaccurate). There is no correlation between the resting level of hemoglobin and the total body hemoglobin or red cell mass.[117,130] Consequently, even though total body hemoglobin does increase in response to training and may correlate with performance, this cannot be determined from a resting blood sample. Measurement of the total hemoglobin or total red cell mass requires collection of a blood sample after strenuous exercise or after administration of epinephrine to mobilize the red cell reserve and the determination of plasma volume using a technique such as Evans blue dye dilution.[117]

These techniques have been used to document red cell hypervolemia in poorly performing, overtrained standardbreds.[117]

Some veterinarians use the resting leukocyte count to monitor fitness, and particularly overtraining, in performance horses.[130] Decreases in the neutrophil/lymphocyte (N/L) ratio have been used to indicate overtraining (training off or adrenal exhaustion). However, the N/L ratio varies in individual horses, depending on when it is determined in relation to the timing and type of exercise and on factors such as age, stress, and disease. Reliable evidence indicates that the N/L ratio is not a good predictor of adrenal status.[131] Indeed, adrenal function in horses with “adrenal exhaustion syndrome” remains to be accurately characterized on the basis of reproducible function tests.

5.8.2.4

SERUM BIOCHEMICAL PROFILES

Biochemistry profiles are commonly used to monitor performance horses and to evaluate those with performance problems. These profiles are useful, but interpretation must take into account that when many measurements are performed, there is a high statistical probability that one or two results will be outside the normal range (95% confidence).[130] If only one or two results on a profile are slightly abnormal, the tests are best repeated on a second sample before the true significance of the result is ascribed. Biochemistry profiles are most useful in detecting horses with subclinical muscle problems (either primary exertional rhabdomyolysis or muscular strain secondary to skeletal problems), liver diseases, renal diseases, and gross disturbances in electrolyte and acid-base regulation. Biochemical profiles usually include aspartate aminotransferase (AST), creatine kinase (CK), LDH, alkaline phosphatase (AP), γ-glutamyltransferase (GGT), sorbitol dehydrogenase (SDH), blood urea nitrogen (BUN), creatinine, sodium (Na), potassium (K), chloride (Cl), bicarbonate, phosphate, calcium (Ca), magnesium (Mg), glucose, and other parameters that are of variable clinical relevance. Studies of horses during training have failed to show any correlation between resting or exercising values for these parameters and fitness.[130] In endurance horses, evaluation of renal fractional excretions of electrolytes may provide better information regarding the horse's electrolyte balance than serum chemistry measurements alone.[132]

5.8.2.5

EVALUATION OF THE RESPIRATORY TRACT

Standard parameters of a routine examination including rectal temperature, respiratory rate, respiratory character, mucous membrane color, and capillary refill time should be carefully evaluated at rest. The presence of nasal discharge, cough, edema, jugular distention or pulsation, or other signs suggesting local or systemic disease should be noted. The larynx, muscular process of the arytenoid cartilages, retropharyngeal area, and trachea should be palpated for size and symmetry. The heart and lungs should be carefully auscultated and percussed at rest, and auscultation of the lungs should be repeated as the horse is induced to breathe more deeply by application of a rebreathing bag. When stridor is part of the history, the upper respiratory tract should receive particular attention in the diagnostic evaluation. Not only must the character of the noise be determined, but the extent of work the patient can tolerate before exhibiting diminished performance must be established, because this helps in the interpretation of abnormalities seen on the endoscopic examination (see Stridor, p. 71). Often the onset and intensity of the stridor coincides with a decrease in work capacity that is typical of certain obstructive airway diseases. Endoscopy, including treadmill endoscopy if facilities permit, and radiography form an important part of the diagnostic evaluation of horses with upper airway abnor-malities[133] (see Respiratory Distress, p. 60, and Stridor, p. 71). The most common abnormalities of the upper airway that cause poor performance include dorsal displacement of the soft palate, dynamic pharyngeal collapse, dynamic

collapse of the left arytenoid cartilage in association with ILH, epiglottic entrapment, pharyngitis, and collapse of the alar folds.[134,135] Diminished performance in horses with mild or subclinical viral infection is probably mediated at least partly by abnormalities in the respiratory tract.[136] If no abnormalities are detected at rest, functional disturbances of airflow may occur during maximum exercise, and these disorders can best be identified by examining the upper airway using video endoscopy during treadmill exercise. The use of Velcro to attach the endoscope to the halter after insertion of the tip of the endoscope to the depth of the guttural pouch openings decreases the blurring of the image that occurs during exercise. Slow-motion playback must be used because many abnormalities occur rapidly with each respiratory cycle. In particular, dorsal displacement of the soft palate and the extent of dynamic laryngeal obstruction with ILH can be more fully evaluated with treadmill exercise tests.[133–135] The presence of inspiratory or expiratory obstruction can be further evaluated during treadmill exercise by introducing transducers via the nostrils to measure airway pressures at the level of the pharynx and trachea.[133,135] During a treadmill exercise test, samples for blood gas analysis can be drawn from extension tubing connected to an 18-gauge, 2-inch catheter inserted into the transverse facial artery.

Further diagnostic evaluation of the lower airways is indicated in horses with an abnormal respiratory rate or character, cough, nasal discharge, abnormal lung sounds, prolonged recovery after application of a rebreathing bag, or a history of EIPH, cough, or respiratory distress with exercise. Horses in which excess mucus or exudate can be demonstrated in the trachea during endoscopy performed after exercise are also candidates for further evaluation. Applicable tests include a complete blood count, tracheal wash or BAL, endoscopy, radiography, and ultrasound examination (see Cough, p. 42, and Stridor, p. 71). Tracheal wash samples collected after exercise are more likely to identify lower airway disease than those collected before exercise.[137] Respiratory viral infection, EIPH, bronchiolitis, hyperreactive airways and recurrent airway obstruction (RAO), and chronic obstructive pulmonary disease (COPD) are all conditions that may not be apparent at rest but that constitute significant causes of exercise intolerance.

78
79

5.8.2.6

EVALUATION OF THE CARDIOVASCULAR SYSTEM

A full evaluation of the mucous membranes, capillary refill time, pulse rate, pulse character and rhythm, heart rate and rhythm, and auscultatory findings is an important part of the evaluation of the performance horse. Failure to maintain cardiac output because of an inability to regulate either heart rate or stroke volume is the mechanism through which cardiac diseases induce exercise intolerance. Many cardiac dysrhythmias and valvular dysfunctions are readily apparent on auscultation of the resting horse. However, the contribution of mild abnormalities to exercise intolerance may require exercise testing. In addition, some arrhythmias and valvular or myocardial dysfunctions can be detected only during or shortly after exercise. Thus resting and exercising electrocardiography and echocardiography before and immediately after exercise are indicated.[133,135] The heart rate can be monitored during exercise using either telemetric electrocardiography or commercial heart rate monitors. Electrocardiograms (ECGs) provide the additional benefit of evaluating both heart rate and rhythm. Supraventricular tachyarrhythmias, the most important of which is atrial fibrillation (AF) in horses, can lead to heart rates exceeding 240 beats/min at submaximal exercise.[138] Under these circumstances, cardiac output may be limited by the decreased time available for diastolic perfusion of the myocardium; the absence of atrial contraction; and the reduced time for passive ventricular filling, leading to reduced stroke volume. Many horses with AF maintain efficient circulation at rest and during light exercise but are intolerant to strenuous exercise because they are unable to increase cardiac output sufficiently at rapid heart rates.[139] Some horses show transient paroxysmal AF during exercise but not at rest.[139] These are often easiest to observe in ECG tracings obtained within 60 seconds after an exercise test. Conversion to sinus rhythm, either spontaneously with quinidine sulfate, or electroconversion[140] usually leads to a return to normal performance

in horses with AF.[141,142] The ability to maintain cardiac output can be compromised by other cardiac arrhythmias such as ventricular tachycardia and ventricular premature depolarization.[135,143] The frequency of premature depolarization can increase with exercise, and the timing of resultant abnormal extra systoles can reduce cardiac output even at submaximal heart rates.[143] Intraatrial block, second-degree atrioventricular (AV) block, and intraventricular block have also been documented in exercise-intolerant, poorly performing horses.[144,145] Horses with cardiac arrhythmias may show abnormal elevations in lactate concentration in response to exercise, indicating a lowered anaerobic threshold, which contributes to exercise intolerance.[118]

Electrocardiography is believed by some veterinarians to be of value in identifying myocarditis. T wave abnormalities (positive and peaked T waves, in contrast to the normal diphasic T waves) in multiple leads on resting ECG traces have been found in a high percentage of horses with a history of fading during the final portion of a race.[144] T waves are highly labile, affected by training status, and the mechanism by which abnormal T waves are generated is uncertain. However, T wave changes have been identified in some horses with myocarditis confirmed at necropsy.[130,145,146] Myocarditis may be more definitively documented by evaluating the distribution of serum isoenzymes of LDH and CK or measurement of cardiac troponin I.[147] Although total LDH concentrations in serum are often normal, with myocarditis the percentage of the LDH_1 isoenzyme may be elevated.[148] A positive correlation has been demonstrated between heart size and racing performance.[145] Electrocardiography has been used to assess performance potential by heart score measurement. The heart score represents the mean QRS duration in leads 1, 2, and 3 expressed in milliseconds and has been strongly correlated with heart weight and prize money won by racehorses.[130,145] The physiologic basis for heart score remains in dispute, and expertise is required to standardize leads and measure QRS complexes.

An *echocardiogram* provides essential information in many cases in which clinical evidence of valvular or myocardial dysfunction is present. The pericardium, the size of the heart chambers, the presence of congenital defects, the function of valvular leaflets, and myocardial contractility all can be assessed (see Chapter 30). Decreased myocardial contractility, regurgitant leaks caused by valvular incompetence, left-to-right shunts, and increases in afterload, such as occurs in aortic stenosis, result in systolic dysfunction and a drop in cardiac output.[149] A pulsed, continuous, or color flow Doppler technique may be necessary to determine the size and significance of any disturbances to flow. Cardiac conditions such as effusive pericarditis and myocardial fibrosis and peripheral vascular conditions that inhibit venous return may interfere with ventricular filling during diastole, resulting in decreased end-diastolic volume, stroke volume, and cardiac output.[149] Measurement of fractional shortening before and immediately after treadmill exercise, when pulse rates are above 100 beats/min, permits documentation of resting and exercise-induced myocardial dysfunction.[135] Contrast angiographic studies may be indicated if congenital or acquired cardiac outflow problems are suspected. Nuclear angiocardiography is also useful for evaluating myocardial contractility, cardiac chamber enlargement, outflow problems, and other abnormalities. Hemodynamic studies, which measure pulmonary capillary wedge pressure, pulmonary driving pressure, and pressure in the right side of the heart and pulmonary artery, have proven useful in detecting early cardiac and pulmonary failure in poorly performing trotting horses. These studies involve the introduction of flow directional balloon-tipped catheters through the jugular vein into awake horses.[148]

5.8.2.7

EVALUATION OF THE SKELETAL SYSTEM

A lameness examination, including appropriate flexion tests and other stress tests, should be completed to help rule out musculoskeletal problems. If lameness is observed, appropriate diagnostic nerve blocks, radiographs, scintigraphy, rectal examination of the bony pelvis and aortoiliofemoral arterial pulses, or ultrasound examinations are indicated to help localize the lameness and determine its cause, significance, and prognosis. Some lameness problems that are evident only at high speed may best be evaluated using treadmill exercise. For example, aortoiliofemoral thrombosis reduces peripheral perfusion but often causes only progressive hindlimb lameness with exercise. Foot balance should be carefully assessed at rest and, if possible, during exercise, because gait changes and subtle lameness related to foot imbalance can adversely affect performance. Dynamic evaluation of hoof balance can be accomplished by examining videotapes recorded from behind the horse while it is exercising on a high-speed treadmill or by trotting the horse over force plates embedded in a firm level surface.[150]

79

80

Subtle lameness can increase the metabolic cost of locomotion by inducing changes in gait and coordination, which accelerate the onset of fatigue. In the same fashion, some horses may have an inefficient gait that reduces their performance capacity. Video imaging systems and gait analysis may play an increasingly important role in identifying these individuals in the future.

5.8.2.8

EVALUATION OF THE MUSCULAR SYSTEM

Primary skeletal muscular limitations on performance may occur as the result of painful conditions such as exertional rhabdomyolysis. In resting samples high serum AST may indicate chronic rhabdomyolysis. Measurement of serum CK 4 to 6 hours after an exercise test is most useful in detecting horses with chronic or subclinical forms of exertional rhabdomyolysis. Serum muscle enzyme concentrations measured in blood samples collected immediately after exercise are often normal, but in horses with chronic exertional rhabdomyolysis significant abnormal elevations may be seen when CK peaks at 4 to 6 hours after completion of exercise. In the past it has been recommended that the exercise test be conducted at a speed and duration of exercise similar to that expected of the horse in competition. However, it has been shown that a 15- to 30-minute test at a slow trot more frequently produces abnormal elevations in serum CK (more than twofold to threefold) in susceptible horses.[151] Standardbred and thoroughbred horses with histories of recent episodes of recurrent exertional rhabdomyolysis and horses with polysaccharide storage myopathy often show a greater than twofold increase over normal resting values in response to an exercise test.[151]

Muscle biopsy is a relatively simple procedure that can prove useful for characterizing the nature of an identified exertional myopathy. However, the procedure is not widely used in the diagnostic assessment of poor performance because the evaluation of samples requires considerable histochemical expertise. Percutaneous techniques using a 6-mm—diameter needle* and local anesthetic are routinely used. The middle gluteal muscle is most often sampled because it is relatively accessible and active at all intensities of exercise.[110,114,152] In adult horses a biopsy is collected at a depth of 2½ to 3 inches from a site 8 inches from the tuber coxae along a straight line connecting the point of the tuber coxae with the base of the tail. Open surgical biopsies are most easily obtained from the semimembranosus or semitendinosus muscle at a site approximately 3 inches below the tuber ischii. After the skin has been shaved and aseptically prepared, lidocaine is injected under the skin. A 2-inch—long incision is made through the skin and fascia, and two parallel incisions, 1 inch long and ½ inch apart, are made vertically in the muscle. The muscle is grasped in one place, to prevent handling artifacts, and the biopsy is first transected proximally, freed to a depth of ¼ inch, then transected distally. The disadvantage

of open surgical biopsies is the recovery period of 1 week that is often required, whereas when the needle biopsy is used horses can immediately begin to exercise. Muscle samples should be sent to a laboratory, where they will be frozen in isopentane that has first been chilled in liquid nitrogen. Commonly used histologic and histochemical stains include adenosine triphosphatase (ATPase) after alkaline and acid preincubations, nicotinamide dinucleotide diaphorase (NADH), periodic acid—Schiff (PAS), and hematoxylin and eosin.

An estimate of the state of training can be made by determining the percentage of type 1, type 2A, and type 2B (or type 2X) muscle fibers as well as the oxidative capacity of skeletal muscle in these small muscle samples. In general, horses suited for short-distance, fast exercise have a greater proportion of fast-twitch fibers in the middle gluteal muscles than horses suited for longer distance events, which have a higher proportion of slow-twitch type 1 fibers.[152] However, there are many successful athletes that do not follow this pattern. The proportion of type 1 to type 2 fibers is thought to be genetically based and cannot be manipulated to a great extent by training, whereas age and training increase the proportion of oxidative fast-twitch type 2A fibers relative to type 2B fibers.[110,114,151] Histochemical assessment of NADH staining or quantitative measurement of enzymes such as citrate synthase in biopsy samples frozen rapidly in liquid nitrogen may provide a guide to the state of aerobic fitness.[149] The use of muscle biopsies in horses with poor performance has also aided in the identification of oxidative enzyme defects in Arabian horses and glycogen storage disorders in quarter horses that can markedly affect performance.[152,153]

* Bergstrom biopsy needle, Mortenson, Copenhagen, Denmark.

5.8.3

Standardized Exercise Testing

Exercise intolerance is ultimately a neuromuscular phenomenon resulting from extreme metabolic stress at the level of the muscle fibers.[11] Under many circumstances premature muscle fatigue occurs secondary to disorders that affect oxygen transport (cardiopulmonary systems) or mechanical efficiency (lameness) (Box 5-20). Standardized treadmill exercise tests are often required to assess the function of these systems at high speeds to determine the primary cause of poor performance and to measure the metabolic response of skeletal muscle relative to work intensity. In a substantial number of cases, poor performance results from related or unrelated disorders in more than one body system, such as dynamic airway obstruction and cardiac dysrhythmia in the same horse.[135]

5.8.3.1

TREADMILL TESTS

Horses often need to be acclimated to a treadmill before representative exercise testing can be performed. Standardbred horses are typically exercised while wearing their usual racing tack, whereas horses of other breeds are typically exercised in a halter or bridle with a lead rope attached to each side. Most horses exercise comfortably on a treadmill after two to four training sessions at speeds that include all gaits to be tested. Breaking into a canter is an important skill to train horses to perform on the treadmill. During one of the training sessions, endoscopy of the upper airway can be performed to evaluate upper airway function during maximal speeds. Two types of standardized exercise tests can be used: a high-speed test, in which horses are accelerated to maximal speed for their normal racing distance, or an incremental test, in which speed is increased every 1 or 2 minutes until fatigue is reached. The incremental exercise test is used most commonly because it includes both submaximal and maximal intensities and is readily reproducible. Many exercise tests are performed with the treadmill set at a 6% to 10% slope to minimize the possibility of injury at top speeds and to ensure that maximum exercise intensity is reached.

Several measurements are possible during treadmill exercise testing. In its simplest form, the heart rate can be monitored after 1 minute at each intensity of exercise using a heart rate monitor, although recording of an ECG during exercise provides additional information about exercise-associated dysrhythmias.[135] Blood samples can also be drawn from a jugular catheter during the final 15 seconds at each speed. A linear relationship between heart rate and speed is expected, with a plateau forming at the maximum heart rate. The maximum heart rate does not change with training, but the speed at which the maximum heart rate is reached should increase with training. As an alternative, a linear regression can be used to determine the horse's speed at a heart rate of 200 beats/min (V_{200}). V_{200} is close to the anaerobic threshold, may predict aerobic capacity, increases with increasing fitness, and has a high individual predictability that allows for early and valid detection of clinical disorders that limit performance.[118,130,154] The speed at which horses reach a maximum heart rate has been proposed as a better measure than V_{200} because it is an absolute rather than a relative measure; however, measurement of maximum heart rate requires a more strenuous exercise test. Parameters such as the velocity at which the whole blood lactate value reaches 4mmol/L (V_{LA4}) and the heart rate at which blood lactate reaches 4mmol/L (HR_{LA4}) can be calculated to evaluate the anaerobic threshold.[118,154] The rate of lactate accumulation may also provide valuable information.

81

5.8.3.1.1

Box 5-20 Causes of Exercise Intolerance That Are Inapparent at Rest

5.8.3.1.1.1

RESPIRATORY CAUSES

5.8.3.1.1.1.1

Obstructive Upper Airway Diseases

5.8.3.1.1.1.1.1

Common Causes

Laryngopalatal dislocation (dorsal displacement of the soft palate)

Dynamic pharyngeal collapse

Dynamic collapse of the left arytenoid cartilage in association with idiopathic laryngeal hemiplegia

Chronic pharyngeal lymphoid hyperplasia

Epiglottic entrapment

Axial deviation of the aryepiglottic folds

Arytenoid chondritis

Paranasal sinus empyema

Paranasal sinus cysts

Guttural pouch infections

5.8.3.1.1.1.1.2 Uncommon Causes

Dynamic collapse of the alar folds

Nasal polyps

Progressive ethmoid hematoma

Subepiglottic cysts

Epiglottic retroversion

Chondroma of the arytenoid cartilages

Fractured laryngeal cartilages

Nasopharyngeal cicatrix

5.8.3.1.1.1.1.3 Congenital

Choanal (posterior nares) atresia or stenosis

Excessive alar folds

Stenotic nares

Abnormalities of the nasal septum

Rostral displacement of the palatopharyngeal arch

Tracheal stenosis, stricture, collapse

5.8.3.1.1.1.2 Lower Airway Diseases

5.8.3.1.1.1.2.1 Common Causes

- Exercise-induced pulmonary hemorrhage (EIPH)
- Recurrent airway obstruction (RAO or COPD)
- Equine herpesvirus types 1 and 4 (EHV-1 and EHV-4)
- Other viral infections (influenza, rhinovirus, adenovirus, reovirus)
- Inflammatory lower airway disease
- Bacterial pneumonia
- Pleuropneumonia, pleuritis

5.8.3.1.1.1.2.2 Uncommon Causes

- Pulmonary abscess
- Pneumoconiosis (e.g., silicosis)
- Interstitial pneumonia
- Diaphragmatic hernia

5.8.3.1.1.2 CARDIOVASCULAR CAUSES

5.8.3.1.1.2.1 Common Causes

- Atrial fibrillation
- Ventricular premature contractions
- Ventricular tachycardia

Mitral insufficiency

Aortic insufficiency

Resting or exercise-induced myocardial dysfunction and reduced fractional shortening

Pericarditis

Aortoiliofemoral arteriosclerosis or thrombosis

5.8.3.1.1.2.2 Uncommon Causes

Ventricular septal defects

Monensin toxicity

Heart block (intraatrial, second- and third-degree atrioventricular and intraventricular)

Endocarditis

Congestive cardiac failure

Ruptured chordae tendinea

Cor pulmonale

Congenital defects

5.8.3.1.1.3 MUSCULOSKELETAL CAUSES

Exertional rhabdomyolysis

Lameness involving limbs, sacroiliac joint, back

Focal muscle strain

5.8.3.1.1.4

METABOLIC AND SYSTEMIC CAUSES

- Anemia
- Fluid and electrolyte imbalances
- Anhidrosis
- Heat exhaustion
- Neoplasia
- Liver disease (pyrrolizidine alkaloid)

5.8.3.1.1.5

GENERAL CAUSES

- Obesity
- Poorly trained horse
- Poor genetic potential
- Administration of illicit medications (doping)

Lactate concentrations can be determined in either whole blood or plasma. Recent studies suggest whole blood lactate may provide a more accurate reflection of lactate accumulation than plasma lactate,[155] because red blood cells actively take up lactate and buffer it, and the type and number of red blood cell lactate transporters differ markedly among horses.

The value of V_{200}, V_{LA4}, HR_{LA4}, and other parameters is that they provide standards against which improvement or deterioration in fitness can be assessed and individual horses can be objectively compared.[118,130,154] Hematocrits can also be easily determined from blood samples obtained at each speed to provide a rough estimate of the number of circulating red blood cells. Blood samples drawn before and 4 hours after exercise for measurement of CK concentration can be used to screen for subclinical exertional rhabdomyolysis.

81

82

Further evaluation of the oxygen transport system can be obtained in laboratories where the sophisticated open-flow gas-collection system necessary to measure oxygen consumption ($\dot{V}O_2$) is available. During the incremental exercise test, a plateau in oxygen consumption eventually is reached, representing maximum oxygen uptake. $\dot{V}O_2$ can be used at submaximal speeds to calculate the oxygen cost of locomotion, and $\dot{V}O_{2max}$, a key indicator of aerobic capacity, can be determined. The cardiopulmonary system can be further

evaluated during exercise by measuring arterial blood gases from the transverse facial artery using an 18-gauge indwelling catheter.[154] An accurate measure of the total red blood cell volume in a horse can be determined using an Evans blue dye dilution technique immediately after maximal exercise.

5.8.3.2 FIELD TESTS

Standardization of field exercise tests is very difficult because weather, track conditions, and other factors influence the amount of work performed. The simplest form of exercise test involves timing a horse exercising maximally over a fixed distance and evaluating heart rate recovery rates at specific time points after exercise. Additional information can be obtained by measuring heart rate during exercise using a cardiotachometer.[130] As fitness improves, the heart rate for a given speed of exercise should be lower. Incremental field exercise tests have been used most successfully in standardbred horses in which the heart rate and blood lactates were measured after several heats at predetermined increases in pace. At speeds above 450m/min, lactate begins to accumulate in the blood during exercise; the precise kinetics of accumulation depends on the horse's fitness and exercise capacity. Fitness responses include a lower heart rate and lactate concentration for the same exercise speed. The value of these measurements is only as good as the standardization of the testing procedures used.

6 Chapter 6 Alterations in Cardiovascular and Hemolymphatic Systems

Sheila M. McGuirk

Virginia B. Reef

6.1 PERIPHERAL EDEMA, PLEURAL EFFUSION, ASCITES

Edema is an abnormal accumulation of extracellular fluid in the interstitial spaces of the tissues or in body cavities that can be generalized or localized. If the fluid accumulation occurs in the pleural cavity, it is referred to as *pleural effusion* or *hydrothorax;* if the fluid accumulation is in the abdominal cavity, it is referred to as *peritoneal effusion* or *ascites*.

Fluid accumulates more easily in those parts of the body where the connective tissue structure is relatively loose. The accumulated fluid tends to gravitate to the dependent areas of the body. In the cow, generalized edema is detected externally by swelling of the submandibular tissue, the brisket, the ventral abdomen, and occasionally the limbs (Fig. 6-1). External manifestation of generalized edema in the horse is frequently in the pectoral region between the front limbs, along the ventral abdomen, in the prepuce in stallions and geldings (Fig. 6-2), in the limbs, and sometimes in the head. Stocking up, or limb edema restricted to the lower limbs, is commonly detected in stabled horses with no underlying disease. Large amounts of fluid may accumulate before clinical signs become evident. External evidence of pulmonary edema (i.e., a frothy, possibly blood-tinged fluid in the nares or expectorated) is rarely detected in large animals (Fig. 6-3). There are numerous causes of edema, including congestive heart failure (CHF) (Boxes 6-1 and 6-2). Edema is a late sign of CHF; other subtle signs of failure may be present before edema appears.

6.1.1 Mechanisms of Edema

Edema is caused by an alteration in the equilibrium between capillary permeability and the forces that govern fluid movements at the capillary level. These forces are as follows:

1. Intravascular hydrostatic pressure
2. Interstitial fluid hydrostatic pressure, which exerts a counterpressure to keep fluid within the capillary
3. Intravascular colloid oncotic pressure exerted by plasma proteins, which favors the resorption of interstitial fluid; the major determinant of colloid osmotic pressure in the capillary is albumin
4. Interstitial fluid colloid osmotic pressure exerted by some proteins in the interstitial fluid, which resists resorption of fluid from the interstitial space
5. Vascular surface area capable of fluid transport
6. Vascular permeability to proteins and water

Activation of complement and liberation of cytotoxic agents such as oxygen radicals, leukotrienes, hydrogen peroxide, platelet-activating factor, and lysosomal enzymes contribute to the endothelial and epithelial damage, causing permeability edema. Subsequent increase in colloid osmotic pressure causes fluid accumulation in the interstitial space. The most common causes of increased capillary permeability are trauma, infection,

endotoxemia, and hypersensitivity (allergic) vasculitis. Topical administration of counterirritants can also cause local increase in capillary permeability. Equine purpura hemorrhagica, the most common vasculitic disease in horses, may in its mildest form have symptoms of mucosal petechiae and plaques of edema or, in severe cases, serum exudation from and necrosis of skin surfaces.

83

84

Fig. 6-1 Cow with brisket, ventral, and udder edema.

Fig. 6-2 Gelding with ventral and preputial edema.

Increased hydrostatic pressure can cause either localized or generalized edema. In horses and ruminants the most common causes of increased hydrostatic pressure are CHF, venous thrombosis, liver disease causing obstruction of the portal venous system, lymphadenopathy, a cranial mediastinal mass, compression bandages, limb immobilization, and topical administration of counterirritants. CHF occurs when there is concomitant pulmonary and systemic vascular congestion. The compensatory salt and water retention increases ventricular diastolic, venous, and capillary pressures, which can result in the formation of generalized edema. Arteriolar vasodilation, caused by release of tissue mediators of inflammation or increased venous pressure resulting from obstruction to venous outflow, can also elevate capillary hydrostatic pressure and result in edema formation.

When the plasma protein concentration decreases from normal to values less than 5 g/dL or albumin concentration is less than 1.5 g/dL, generalized edema may occur. Hypoproteinemia can result from (1) decreased production of plasma proteins with starvation, liver disease, or severe heart failure, or (2) augmented loss of plasma proteins resulting from kidney disease, protein-losing enteropathies (Johne's disease, chronic inflammatory bowel disease), peritonitis, or pleuritis. Hemodilution as a result of overzealous administration of fluids or decreased elimination of fluid can cause edema. Failure to excrete adequate water to maintain fluid balance can result from decreased glomerular filtration as a result of kidney disease or heart failure. 84 85

6.1.1.1

Box 6-1 Causes of Peripheral Edema, Pleural Effusion, and Ascites in Horses

6.1.1.1.1

COMMON CAUSES

Chronic heart failure

Mitral or tricuspid regurgitation

Aortic regurgitation

Vegetative endocarditis

Congenital heart defects

Cardiomyopathy

Vitamin E, selenium deficiency

Pericarditis

Pleuritis

Neoplasia: lymphosarcoma

Hypoproteinemia

Liver disease

Gastrointestinal malabsorption: inflammatory bowel disease, neoplasia, parasitism

Peritoneal or pleural effusion

Vasculitis

Equine infectious anemia

Purpura hemorrhagica

Equine ehrlichiosis

Equine viral arteritis

Thrombophlebitis

Lymphatic obstruction

Ulcerative lymphangitis

Lymphadenitis (*Corynebacterium pseudotuberculosis* abscesses)

Trauma

6.1.1.1.2 UNCOMMON CAUSES

Aortic cardiac fistula

Heart base tumor other than lymphosarcoma

Cranial mediastinal mass

Neoplasia: plasma cell myeloma, squamous cell carcinoma, fibrosarcoma

Starvation

Kidney disease: glomerulonephritis, amyloidosis

Ionophore toxicity

Copper deficiency

Counterirritant application

Hemodilution

Pregnancy

Ruptured bladder

Cassia occidentalis toxicity

Fig. 6-3 Gelding with acute fulminant pulmonary edema.

6.1.1.2

Box 6-2 Causes of Peripheral Edema, Pleural Effusion, and Ascites in Ruminants

6.1.1.2.1

COMMON CAUSES

Chronic heart failure

Mitral or tricuspid regurgitation

Vegetative endocarditis

High-altitude disease (brisket disease)

Congenital heart defects

Cor pulmonale

Vitamin E, selenium deficiency

Pericarditis (traumatic reticulopericarditis)

Pleuritis

Heart base tumor: lymphosarcoma

Hypoproteinemia

Liver disease

Kidney disease: amyloidosis, glomerulonephritis

Gastrointestinal malabsorption: lymphosarcoma, Johne's disease, parasitism

Peritoneal or pleural effusion

Lymphatic obstruction (*Corynebacterium pseudotuberculosis*, lymphosarcoma)

Thrombophlebitis

Urolithiasis: ruptured urethra or bladder

6.1.1.2.2

UNCOMMON CAUSES

Eperythrozoan wenyoni (B)

Idiopathic pericardial effusion

Cardiomyopathy

Starvation

Hemodilution

Ionophore toxicity

Copper deficiency

Infectious myocarditis

Vasculitis

Trauma

Pregnancy

Caudal vena caval thrombosis

Ehrlichiosis

Gossypol toxicity

Cassia occidentalis

Phalaris species toxicity

Oxytropis sericea (locoweed) toxicity

Increased tissue colloid osmotic pressure is rarely a cause of edema in horses and ruminants. Interstitial fluid has a lower plasma protein concentration than plasma. When capillary permeability is increased or when abnormal protein-like material is present in the interstitial space, edema can develop by this mechanism. The latter may occur with infection or after administration of topical counterirritants.

Lymphedema occurs when lymphatics are absent or obstructed. Congenital absence of lymphatics is extremely rare. Obstruction to lymphatic drainage can be caused by tumor, local inflammation (lymphangitis or lymphadenitis), or elevated central venous pressure as in heart failure.

6.1.2

Approach to Diagnosis of Peripheral Edema, Pleural Effusion, and Ascites

1 Take history. Note especially history of deworming program, diet, and vitamin or mineral supplements. Determine onset, progression, and duration of the problem and whether other animals are affected. Ask about history of fever, signs of respiratory disease or difficulty, appetite, consistency of feces, and previous medications. Establish the function of the animal and whether there have been changes in performance capability. Compare growth and activity level to that of peers.

2 Perform a physical examination and record vital signs. Determine whether edema is localized or generalized. Palpate external lymph nodes. Palpate edematous areas to determine whether there is heat, pain, or fluid exudation. Edema is typically cool, nonpainful, and pitting, leaving an indentation when a finger is pushed against it. Carefully auscultate heart and lungs. Note abnormalities in cardiac rhythm, murmurs, or other sounds associated with the cardiac cycle. Palpate a peripheral pulse; observe mucous membranes for color, capillary refill time, and petechiae. Observe the jugular vein for distention and pulsations. Evaluate peripheral veins, including the mammary vein, for distention and pulsations. Perform a rectal examination to determine whether internal lymph nodes are enlarged. Palpate the aorta and iliac arteries for pulse strength and fremitus.

3 Obtain blood for the following:

- a Complete blood count (CBC) (includes fibrinogen and plasma protein concentration)
- b Selenium concentrations if cardiomyopathy is suspected
- c *Ehrlichia equi* morula in granulocytes or *Ehrlichia* DNA by polymerase chain reaction if edema, petechial hemorrhages, fever, icterus, or muscle stiffness is present

4 Test serum for the following:

- a Albumin and globulin concentrations
- b Muscle enzyme (creatine kinase [CK], including creatine kinase, myocardial bound [CK-MB] [isoenzyme]; cardiac troponin I [cTnI]; and aspartate aminotransferase [AST]) concentrations
- c Liver enzyme concentrations and liver function (AST, sorbitol dehydrogenase [SDH], alkaline phosphatase, γ-glutamyltransferase [GGT], bilirubin, and bile acid concentrations); values may be elevated in CHF
- d Tests for kidney function as follows: serum urea nitrogen (SUN) and creatinine concentrations, serum electrolyte (Ca, P, Na, K, Cl) concentrations, fractional excretion of electrolytes (see Chapter

34 for method), urinalysis; serum concentrations of Na may be decreased, and SUN may also be elevated in chronic heart failure

e Check for antibodies to equine infectious anemia virus by agar gel immunodiffusion (AGID) or Coggins' test

f Determine titers to equine viral arteritis by serum neutralization if there is ocular inflammation, nasal discharge, abortion, or fever with edema

g *E. equi* antibodies as demonstrated by immunofluorescence if physical examination reveals icterus and fever with edema

h Vitamin E levels if cardiomyopathy suspected

5 Record an electrocardiogram (ECG) to rule out an arrhythmia or conduction disturbance (see Chapter 30); if abnormalities of the ECG are noted, an echocardiogram should be performed.

6 Perform two-dimensional (2-D), M-mode, and Doppler echocardiography if there is a cardiac murmur that is not localized to the left heart base, that radiates, is greater than 2/6 intensity, or is of significant duration.

85

86

7 Analyze fluid to rule out peritonitis, pleuritis, and pericarditis; if physical examination and CBC findings are compatible, examine:

a Pleural fluid

b Pericardial fluid

c Peritoneal fluid

8 Isolate virus from nasopharyngeal swabs, buffy coat, or semen for equine viral arteritis if clinical signs are compatible.

9 Oral D-xylose or glucose absorption test should be done in horses if there is hypoproteinemia and if starvation, renal disease, hepatic disease, pleuritis, peritonitis, infectious gastrointestinal disease, and hemodilution have been ruled out; these tests are not useful in ruminants unless intraabomasal instillation of D-xylose or glucose is accomplished.

6.2 CARDIAC ARRHYTHMIAS

Cardiac arrhythmias are abnormalities in the normal heart rate, rhythm, or conduction pattern. Arrhythmias result from abnormalities of impulse generation or impulse conduction or a combination of both. In the normal heart the impulse is generated in the sinus node because it has the highest rate of spontaneous depolarization. Atrial contraction is followed shortly by ventricular contraction. There is variability in reported normal ranges for heart rate in the large adult animal species, but there is general acceptance of the following ranges:

- Horses: 26 to 50 beats/min; 60 to 80 beats/min in foals
- Cattle: 49 to 84 beats/min
- Sheep and goats: 70 to 90 beats/min

Arrhythmias are more common in horses than in other domestic animal species. As many as 25% of horses that have no other signs of heart disease have cardiac arrhythmias during routine examination or electrocardiography.[1] During continuous 24-hour electrocardiography, 44% of normal horses had second-degree atrioventricular (AV) block, 10% had sinus arrhythmia, 3% had sinoatrial (SA) block, 27% had occasional supraventricular extrasystoles, and 15% had occasional ventricular arrhythmias.[2] Cardiac arrhythmias may be present in 40% of horses that have other signs of cardiac disease.[1] Unlike other species, the horse has arrhythmias at rest that are considered benign or functional. Benign, physiologic, or functional arrhythmias are usually bradyarrhythmias and are thought to be the result of increased vagal tone. These arrhythmias disappear at high heart rates (exercise or excitement) or with the administration of atropine (0.02 to 0.05 mg/kg subcutaneously [SC] or intramuscularly [IM]) or glycopyrrolate (0.003 to 0.006 mg/kg SC or IM). Some examples of benign or functional arrhythmias are as follows:

- Second-degree AV block
- Sinus arrhythmia
- Sinus bradycardia
- SA block
- SA arrest

Other arrhythmias are usually considered to be pathologic, even if there are no other overt signs of cardiac disease. Some examples of pathologic arrhythmias are:

- Atrial fibrillation
- Atrial and ventricular premature depolarizations
- Supraventricular or ventricular tachycardia
- Advanced second-degree or third-degree (complete) AV block

The most effective method of identifying the specific arrhythmia is by performing an ECG. Arrhythmias that are transient or intermittent may not be detected with resting electrocardiography. Radiotelemetry or continuous 24-hour ECG recordings are useful to characterize the type, frequency, and severity of arrhythmias. Exercising electrocardiography may identify arrhythmias that are absent or clinically insignificant at rest but that may impair performance.

In general, cattle do not have benign arrhythmias like horses, but they are frequently found to have sinus bradycardia and sinus arrhythmia associated with lack of feed intake. These arrhythmias were previously thought to be abnormal and associated with vagal indigestion but have been shown to occur in normal cattle held off feed for 12 to 48 hours.[3] Cattle with gastrointestinal disease seem to have increased susceptibility to cardiac arrhythmias, especially atrial premature depolarizations and fibrillation. Although the reason for the susceptibility is not established, abnormal electrolyte concentrations, acid-base disturbances, and aberrations in autonomic nervous system balance have been proposed.[4,5] Sinus arrhythmia in goats is considered to be a benign arrhythmia and is present in many normal animals. Normal camelids also frequently have sinus arrhythmia.

6.2.1

Mechanisms of Cardiac Arrhythmias

Arrhythmias result from abnormalities of impulse generation or impulse conduction or a combination of both. A variety of mechanisms can cause abnormal impulse generation or conduction (Boxes 6-3 and 6-4). Abnormal impulse generation occurs because of localized changes in ionic currents that flow across the membranes of single cells or groups of cells. Abnormal impulse generation can be seen as automaticity (normal and abnormal) or triggered activity.

Automaticity, the ability to initiate action potentials spontaneously, is a property of cells in the sinus node, some parts of the atria, the AV junction, and the His-Purkinje system. Cardiac disease can be responsible for the development of automaticity in cells that normally do not have this property. Normal automaticity develops when the membrane potential slowly falls (i.e., becomes less negative) during diastole. When the membrane reaches its threshold potential, an impulse is initiated. The most common clinical arrhythmias that are thought to be caused by the automaticity mechanism are sinus tachycardia and sinus bradycardia, which are the result of alterations in autonomic nervous system tone. Enhanced automaticity in another area of the heart that is capable of automaticity (spontaneous depolarization) may be responsible for atrial or ventricular premature beats. It is not clear what clinical arrhythmias are caused by triggered activity.

6.2.1.2.2

UNCOMMON CAUSES

Ionophore toxicity

Anesthesia

Hypoxemia

Cardiomyopathy

Autonomic imbalance

Under certain circumstances, conduction abnormalities allow a propagating impulse, which has already excited the heart, to persist and reexcite the atria or ventricles after the end of the refractory period. This can occur in an ordered or random fashion. Random reentry occurs over reentrant pathways that continuously change in size and location with time, whereas ordered reentry occurs over a relatively fixed reentrant pathway. Impulse propagation may be slow enough that reentrant circuits can be established in very small areas of myocardium. In large animals the size of the myocardial circuit is large enough that relatively mild alterations in impulse propagation may make reentry feasible and may account for the relatively greater frequency of arrhythmias in these species. Although it is not possible to precisely define the mechanism of clinical arrhythmias, it is believed that atrial and ventricular fibrillation may be caused by random reentry.

Under clinical conditions, cardiac arrhythmias may be associated with disturbances in electrolyte concentrations, especially potassium and calcium, in acid-base balance, and in autonomic nervous system balance. These

conditions can precipitate cellular changes conducive to the development of arrhythmias by any of the above mechanisms.

6.2.2 Approach to Diagnosis of Cardiac Arrhythmias

It is important to distinguish between abnormal arrhythmias that are primary and those that are secondary. Most abnormal arrhythmias of horses and cattle are tachyarrhythmias. Primary arrhythmias are caused by pathologic conditions of the heart (myocarditis, valvular disease, conduction system abnormalities, and pericarditis). Secondary arrhythmias develop in the absence of heart disease and can be caused by excitement, fever, sepsis, hypoxemia, metabolic or electrolyte imbalances, gastrointestinal disturbances, anesthesia, ionophores, other drugs, or toxemia. The treatment and prognosis for the two types of arrhythmias can be very different, and examination and laboratory tests are used to assist in making the distinction.

1. Take history. Determine the diet, feed additives, or medication (including furosemide, bicarbonate, or other prerace medications); note whether there has been exercise intolerance, syncope, fever, coughing, or edema; inquire about gastrointestinal problems, diarrhea, or colic; inquire about access to cattle or chicken feed or supplements and about previous respiratory tract infections in this animal or stablemates.

2. Perform a physical examination to determine whether there is primary cardiac disease. Record the animal's vital signs. Determine whether this is a bradyarrhythmia or tachyarrhythmia. Careful auscultation should note which heart sounds are present and should characterize the arrhythmia. There may be irregularities in the basic rhythm, added sounds, or long pauses; classification of heart rate by regularity of rhythm can distinguish one arrhythmia from another (see Chapter 30). Note whether a pulse deficit is present by simultaneous auscultation and palpation of the peripheral arterial pulse; note the strength of the peripheral arterial pulse; observe the jugular vein for pulsations and distention; examine peripheral veins for distention; and examine mucous membrane color and capillary refill time. Careful auscultation of the lungs with and without a rebreathing bag should be performed.

3. Record an ECG. The base-apex lead can be used to screen for arrhythmias; it is attached using positive, negative, and ground leads as follows:

    a. Positive lead is attached to skin over the left fifth intercostal space at the point of maximal intensity (PMI) of the apex beat; using lead I, this is the left arm electrode; using lead II or lead III, it is the left leg electrode.

    b. Negative lead is attached to the skin of the right jugular furrow two thirds of the distance from the ramus of the mandible to the thoracic inlet; using lead I or lead II, this is the right arm; using lead III, it is the left arm. ECG interpretation is discussed in Chapter 30.

4. If there is a cardiac murmur, perform an echocardiogram (including 2-D, M-mode, and Doppler). Look for evidence of ventricular dysfunction, myocardial failure, chamber dilation, tumor, valvular abnormalities such as endocarditis, congenital defects, aortic cardiac fistula, and pericardial effusion.

5. Obtain feed for analysis if ionophore (monensin, lasalocid, salinomycin) exposure is suspected.

6. Obtain blood for the following:

    a. CBC

    b. Selenium concentrations if cardiomyopathy suspected

c Blood gas determinations and acid-base status

7 Test serum for the following:

a Electrolyte (Na, K, Cl, Ca, Mg, P) concentrations

b Vitamin E (α-tocopherol) concentration

c Cardiac isoenzyme determinations of CK (CK-MB) and cardiac troponin-I (cTnI)[6] if myocarditis or myocardial necrosis is suspected

8 Test urine for the following:

a Electrolyte (Na, K, Cl) concentrations

b Creatinine determination

9 Calculate fractional excretion of potassium in the urine. This will be variable, depending on the diet, but a low value indicates the need for supplementation.

10 Treat the arrhythmia if:

a Patient is hemodynamically unstable (e.g., poor cardiac output, weak peripheral pulses, cold extremities, syncopal)

b There is ventricular tachycardia with a rapid rate (heart rate >100 beats/min for horses and >120 beats/min for cows)

c There are multifocal ventricular ectopic beats

d A QRS is detected in the preceding T wave (R on T)

e There are more than 15 extra systoles per minute

f There is advanced second-degree or complete (third-degree) AV block

g The primary problem is cured or the condition is stabilized, and the patient is symptomatic with the cardiac arrhythmia

6.3 CARDIAC MURMURS

Throughout the cardiovascular system, blood has a laminar or streamlined flow, except in the heart and sometimes in the aorta. Occasionally conditions occur that cause turbulent flow that is sufficient to cause resonance in adjacent structures. This resonance may be heard as a murmur when a critical level of turbulence is reached (Boxes 6-5 and 6-6). The factors that determine whether blood flow is laminar or turbulent are related by the Reynolds number, which is the ratio of the inertial to viscous forces. When the Reynolds number exceeds a critical value (about 2000 in large vessels), turbulence occurs. Increased flow velocity or reduced blood viscosity (e.g., anemia) predisposes to murmur development. The characteristics of the murmur depend on the velocity of the blood flow and the nature of the structures that are caused to vibrate.

It is useful to characterize murmurs with regard to timing in the cardiac cycle (systolic, diastolic, or continuous), duration in the cardiac cycle (early, mid, late, holo-, pan-), intensity (loudness), shape and quality or frequency, PMI, and radiation of the murmur. Systolic murmurs occur anytime between the first and second heart sound. Diastolic murmurs occur between the second and first heart sounds. Continuous murmurs occur throughout the cardiac cycle (Fig. 6-4). The intensity of murmurs is frequently graded on a scale of 1 to 6[7]:

- *Grade 1* is a soft murmur heard only after minutes of careful listening.
- *Grade 2* is a soft murmur heard immediately on auscultation.
- *Grade 3* is a murmur of moderate intensity.
- *Grade 4* is a loud murmur associated with a palpable thrill.
- *Grade 5* is a loud murmur that is not heard when the stethoscope is removed from the chest wall.
- *Grade 6* is a loud murmur that is audible with the entire stethoscope chest piece held away from the chest wall.

6.3.2.2 UNCOMMON CAUSES

Cardiomyopathy

Myocarditis

The PMI of a murmur usually corresponds to the location of one of the heart valves. Murmurs associated with the mitral valve will frequently be heard best in the left fifth intercostal space just dorsal to the level of the elbow. These murmurs usually radiate dorsally or toward the aortic valve area. Pulmonic valve and aortic valve murmurs are best heard at the base of the heart. For this area to be accessed, the hand is moved under the left triceps muscle to the third and fourth intercostal spaces just below the level of the shoulder. Aortic valve murmurs are located just dorsal and caudal to the pulmonic valve. Murmurs associated with the tricuspid valve are frequently located in the right third or fourth intercostal space between the shoulder and elbow.

Most systolic murmurs fall into one of two categories: ejection or regurgitant (see Fig. 6-4). Systolic ejection murmurs are caused by obstructed, increased, or turbulent blood flow across normal or damaged semilunar valves. Valvular obstruction is rare in large animals, but functional ejection murmurs are commonly found in healthy horses. The PMI of the functional murmur is typically at the pulmonic or aortic valve or just dorsal to them over the great vessels. It is a crescendo-decrescendo murmur that is audible in early-to-mid systole. The diagnostic considerations for systolic ejection murmurs are given in Box 6-7. The innocent or functional murmur may be distinguished from a pathologic murmur by being of lower and variable intensity, peaking in early-to-mid systole, ending well before the second heart sound, and having no radiation. The physiologic systolic ejection murmur may disappear or become louder after exercise. Diagnostic considerations for systolic regurgitant murmurs are listed in Box 6-7.

Regurgitant murmurs typically begin with AV valve closure and end after pulmonic and aortic valve closure, making the second heart sound inaudible. They can be variable in duration, however, and occur in early, mid, or late systole or can be pansystolic or holosystolic. Location of the PMI and the direction of radiation of the systolic murmur distinguish mitral or tricuspid regurgitation from a ventricular septal defect (VSD). Systolic clicks are rare in horses and cattle but may indicate abnormalities of the chordae tendineae, AV valve prolapse, or dilation of the aorta.

88

89

Fig. 6-4 Phonocardiographic characteristics of systolic ejection, holosystolic (pansystolic) regurgitant, and diastolic decrescendo cardiac murmurs.

6.3.3.2 REGURGITANT

Mitral regurgitation

Tricuspid regurgitation

Ventricular septal defect

Tetralogy of Fallot

Diastolic murmurs can occur between S_4 and S_1 (atrial systolic murmurs), between S_2 and S_3 (ventricular filling murmurs), or from S_2 to S_1 (aortic regurgitation or rarely, pulmonic regurgitation). Both the atrial systolic and ventricular filling murmurs are usually functional, can be heard over the left or right hemithorax, and can vary in intensity. The aortic regurgitation murmur is typically a decrescendo murmur with its PMI over the aortic valve that begins immediately after S_2 (see Fig. 6-4). Some aortic regurgitation murmurs can be harsh or musical, associated with high-frequency vibrations of an aortic valve leaflet, and they may be audible over the right thorax.

Continuous murmurs are uncommon in horses and ruminants. Patent ductus arteriosus, a finding in normal foals for a short time after delivery, can be heard in the left third intercostal space. This murmur can be continuous, but more frequently only a residual systolic murmur is audible.[8] Continuous machinery murmurs are most frequently reported in adult horses with an aortic cardiac fistula secondary to rupture of the aortic root or of a sinus of Valsalva aneurysm. A continuous “washing machine” murmur, which is most easily heard over the left cardiac area, is associated with traumatic pericarditis in cattle and is caused by the accumulation of fluid, gas, and fibrin within the pericardium. Acquired systolic and diastolic murmurs in adult horses or cattle are usually the result of separate murmurs.

6.3.4 Approach to Diagnosis of Cardiac Murmurs

1 Take a history. Note the age, onset, duration, and progression of the condition. Determine exercise capability, growth, and attitude; inquire about previous fever, illness, or medications.

2 Perform a physical examination. Record the animal's vital signs. Determine timing, duration, intensity, location of PMI, shape, and radiation of murmur. Palpate peripheral arterial pulse and observe jugular vein for distention and pulsations. Carefully auscultate the lungs at rest and during deep inspiration.

3 Obtain blood for CBC (includes fibrinogen and total plasma protein concentration).

4 Test serum for the following:

a Electrolyte concentrations

b Bovine leukosis virus (BLV), AGID status (cows)

c Cardiac isoenzyme determinations of CK (CK-MB) and cTnI[6] if myocarditis or myocardial necrosis is suspected

5 Record an ECG.

6 Perform a phonocardiogram to confirm timing and shape of murmur, if available.

7 Perform an echocardiogram to look for valve abnormalities, abnormalities of the aortic root, congenital defects, chamber enlargement and wall motion abnormalities; use pulsed wave and color flow Doppler echocardiography to localize the shunt, regurgitant blood flow, or stenosis (rare); use color flow and continuous wave Doppler echocardiography to estimate the severity of the jet associated with a shunt, valvular regurgitation, or stenosis (rare); contrast echocardiography can be used for examination of congenital defects and detection of an aortic cardiac fistula and some valvular insufficiency.

8 Take radiographs to find evidence of pulmonary edema or pleural effusion.

9 Perform thoracic and abdominal ultrasonographic examinations to find pleural effusion, peritoneal effusion, and evidence of pulmonary edema or hepatic congestion.

10 Cardiac catheterization for pressures, oximetry, or angiocardiography may complement data obtained noninvasively with Doppler echocardiography.

6.4 MUFFLED HEART SOUNDS

Auscultation of heart sounds requires that the vibrations generated by the heart be transmitted through the tissues of the thorax to the outer chest wall with sufficient amplitude to be heard. Blood transmits sound very well, whereas lung tissue strongly attenuates sound waves. The chest wall itself causes attenuation of the sound that is most significant at the interface between bone and muscle. Therefore physical factors in a normal patient, such as a large, thick chest or obesity, can cause heart sounds to be muffled. If the environment for auscultation is conducive to hearing heart sounds, other factors such as stethoscope quality may cause muffling of heart sounds in a normal patient. One should strive to have a stethoscope with comfortably fitting earpieces, thicker and shorter tubing, a rigid

diaphragm to hear S_1, S_2, and higher-frequency sounds, and a bell piece for auscultation of S_3, S_4, low-frequency sounds, and murmurs.

Heart sounds are muffled primarily because of displacement of the heart from the thoracic wall by fluid (pericardial effusion), a soft-tissue mass (abscess or tumor), or air (pneumothorax, pneumomediastinum, or emphysema) (Boxes 6-8 and 6-9). Rarely is muffling of heart sounds attributed to weak cardiac contractions alone, although this may be a finding in recumbent cows with marked hypocalcemia.

6.4.1

Approach to Diagnosis of Muffled Heart Sounds

1. Take a history. Inquire about any change in attitude, appetite, diet, or posture; determine whether a magnet has been administered to cattle; note any history of fever, weight loss, respiratory disease, colic, or diseases of other body systems and the deworming history; determine whether cattle are known to be BLV positive.

2. Perform a physical examination and determine vital signs. Carefully auscultate the lungs to establish whether there is ventral dullness or evidence of increased or added sounds from pulmonary parenchymal compression; carefully auscultate the heart for pericardial friction rubs; determine whether there are signs of CHF (jugular venous distention, peripheral edema); percuss the thorax to determine whether there is emphysema, pleural fluid, or pneumothorax; note that pleural fluid in the absence of pericardial effusion causes radiating heart sounds but absence of airway sounds; determine whether there is thoracic and/or abdominal pain; in cattle, check for presence of a reticular magnet using a compass or stud finder.

3. Obtain blood for the following:

    a. CBC

    b. Fibrinogen concentration

    c. Plasma or serum protein concentration

    d. Liver enzymes and tests for liver function (AST, SDH, alkaline phosphatase, GGT, bilirubin, and bile acid concentration)

    e. Tests for kidney function (urinalysis, creatinine, blood urea nitrogen [BUN], Na, K, Cl, P concentrations and fractional excretion of Na, Cl, P)

4. Test serum for BLV serology and for equine influenza, viral arteritis, and herpesvirus.

5. Take radiographs of the thorax to determine whether there is pulmonary parenchymal and/or pleural or pericardial disease.

6. Perform an ECG.

7. Perform a thoracic ultrasound examination to determine if there is pericardial or pleural fluid, a cardiac mass, or a mass in the cranial mediastinum compressing the heart. Determine the location and type of fluid present.

8. Analyze pericardial or pleural fluid, and perform culture and sensitivity testing if indicated.

6.5 CARDIOVASCULAR EXERCISE INTOLERANCE, WEAKNESS, AND SYNCOPE

Exercise intolerance, weakness, or syncope can be a clinical sign associated with disease in many body systems. Exercise intolerance can be manifested as sudden deceleration or stopping, failure to perform at an expected level, a sudden change in the level of performance or production, lowered enthusiasm for work, cough on exertion, evidence of respiratory distress, or excessive sweating. Weakness can be manifested as recumbency, difficulty in rising from recumbency, muscle tremors or fasciculations, reluctance to move, or toe dragging. Syncope is a sudden collapse and loss of consciousness (fainting).

6.5.1 Mechanisms of Cardiovascular Exercise Intolerance, Weakness, and Syncope

The clinical signs of exercise intolerance, syncope, or weakness can be caused by cardiovascular disease (Boxes 6-10 and 6-11). They are the result of failure to maintain cardiac output, caused by inability to regulate either heart rate or stroke volume. A normal horse increases cardiac output at submaximum heart rates (less than 210 beats/min in horses) primarily by tachycardia. At maximum heart rates (approximately 210 to 240 beats/min in horses), subsequent increments in cardiac output occur by increased stroke volume.[9] The maximum heart rate for cattle and small ruminants has not been published.

Supraventricular cardiac arrhythmias, primarily atrial fibrillation in horses, can lead to heart rates greater than 240 beats/min with submaximum exercise.[10,11] Heart rates exceeding the maximum rate may limit cardiac output by decreasing the time for diastolic perfusion of the myocardium or by limiting stroke volume because the short diastolic intervals leave inadequate time for ventricular filling. The ability to maintain cardiac output can also be compromised by other cardiac arrhythmias such as ventricular premature systoles. The frequency of extrasystoles can increase with exercise, and the timing of the abnormal beats can reduce cardiac output even at submaximum heart rates.[12] Horses with cardiac arrhythmias can have abnormal elevations in lactate concentration in response to exercise, indicating a lower anaerobic threshold and leading to exercise intolerance.[13,14]

6.5.1.2.1

COMMON CAUSES

Myocardial disease

Cardiac arrhythmias

Congenital heart defects

Chronic heart failure

* See Chapters 8 and 13 for additional noncardiac causes.

Cardiac output maintenance may also be compromised in animals by diseases affecting myocardial contractility or diseases that result in increased end-systolic volume despite a submaximum heart rate.[15] Diseases that result in decreased venous return (peripheral vascular disease) can also reduce cardiac output and cause signs of exercise intolerance, weakness, or syncope.

Exercise intolerance or weakness can also be caused by painful peripheral vascular conditions or conditions causing peripheral hypoxia or lactic acid accumulation. In horses such conditions may exist with aortoiliac

thrombosis. Sudden episodes of weakness and collapse without change in consciousness are associated with hyperkalemic period paralysis in horses (see Chapter 42).

Syncope may be associated with epilepsy or other central nervous system (CNS) disturbance. If cardiovascular and pulmonary function appears normal, the nervous system should be examined in detail (see Chapter 8). Collapse during exercise is most commonly caused by cardiovascular disease, whereas collapse at rest is usually associated with neurologic disease.

6.5.2 Approach to Diagnosis of Exercise Intolerance, Weakness, and Syncope

1. Take history. Establish onset of problem, previous performance history, and activity level when clinical signs are observed. Determine whether there is coughing, dyspnea, or excessive sweating associated with stress or exercise.
2. Perform a physical examination and record vital signs to determine whether lameness or respiratory or neurologic disease is the cause of these clinical signs. Of particular importance are heart rate at rest, peripheral arterial pulse characteristics, presence of pulse deficits, mucous membrane color, and appearance of jugular venous pulses. Lungs should be auscultated for evidence of pulmonary edema or pleural effusion. The chest should be percussed. Rectal examination should be performed to evaluate aortic and iliac arterial pulses; metatarsal artery pulses and saphenous vein refill should be evaluated.
3. Perform a rectal ultrasound examination if aortoiliac thrombosis is suspected, to document the disease and assess its severity.
4. Record an ECG at rest, during exercise (preferably with radiotelemetry), and after exercise, if it is safe for the animal to exercise. Perform a continuous 24-hour ECG to evaluate frequency of arrhythmias.
5. Perform an echocardiogram (2-D, M-mode and Doppler) to evaluate size of heart chambers; to look for congenital defects, acquired valvular heart disease, and pericardial disease; and to evaluate myocardial contractility and ventricular wall motion.
6. Perform a stress echocardiogram before and after exercise to evaluate changes in myocardial contractility and ventricular wall motion with exercise.
7. Perform an exercise test to measure a parameter of lactic acid concentration (i.e., lactic acid accumulation after exercise test, lactic acid concentration at defined velocity of exercise, or velocity of exercise at a defined lactic acid concentration), arterial blood gas concentrations, preexercise and postexercise CK levels, cTnI, and exercise endoscopy to make an upper airway evaluation.

6.6 VENOUS DISTENTION AND PULSATIONS

The jugular venous pulsations observed in the neck are primarily a reflection of right atrial and right ventricular activity. There may be some small contribution from carotid arterial impact.[16] The jugular venous pulse reflects the right atrial or central venous pressure, which is influenced by blood volume, right ventricular cardiac output, and right atrial contractility (Boxes 6-12 and 6-13). Jugular venous pulsations are observed in normal animals, but the pulse seldom radiates more than one third of the distance from the thoracic inlet to the ramus of the mandible when the head is held in a normal, upright position.

6.6.1

Mechanisms of Venous Distention and Pulsations

The normal jugular venous pulse consists of three positive and two negative deflections (Fig. 6-5). The first and dominant positive wave is the A wave, produced by atrial contraction. During atrial relaxation the pressure declines until ventricular systole. The second positive deflection is the C wave, which is produced by the bulging of the tricuspid valve leaflets into the right atrium during early (isovolumetric) right ventricular systole. Carotid arterial impact on the jugular vein may also contribute to the C wave.[16] As the ventricle contracts, the plane of the tricuspid valve is pulled toward the apex of the heart and the atrial pressure declines, producing the X descent. The X descent is terminated by the V wave, which is associated with venous return, subsequent atrial filling, and a closed tricuspid valve. At the end of ventricular systole, the atrial pressure falls again as a result of tricuspid valve opening and rapid right ventricular filling. This is the Y descent. The Y descent is terminated as the pressure gradually rises with right-sided heart filling.

Abnormal pulsations occur with increased resistance to right ventricular filling, regardless of the cause. Distention and pulsations in the jugular vein are usually associated with an elevated right ventricular pressure, such as occurs in right-sided heart failure, constrictive pericarditis, or, more rarely, cardiomyopathy. Prominent jugular pulsations are noted with tricuspid regurgitation and certain cardiac arrhythmias, especially those arrhythmias associated with atrial contraction against a closed AV valve. The carotid arterial pulse can mimic jugular venous pulsations. To distinguish among the causes of jugular venous pulsations, lightly compress but do not occlude the jugular vein at the thoracic inlet. The jugular vein will distend enough to eliminate carotid arterial pulsations. If pulsations are still present, tricuspid regurgitation, atrial arrhythmias, or right-sided heart failure should be considered. If the jugular vein is compressed near the ramus of the mandible and massaged toward the thoracic inlet, refilling is indicative of tricuspid regurgitation. Jugular venous distention without pulsations can occur with compression of the cranial vena cava from a cranial thoracic or mediastinal mass or from occlusion of the jugular vein with a thrombus.

6.6.2 Approach to Diagnosis of VenousDistention and Pulsations

1 Take history. Note especially history of respiratory disease, exposure to high altitude and locoweed, or ingestion of potential cardiotoxins. Determine whether other animals have been similarly affected, whether the BLV status of affected cattle is known, and whether a magnet has been administered.

2 Perform a physical examination. Determine whether there is tachypnea or tachycardia. Carefully auscultate for abnormal heart sounds, rhythm, or intensity of sounds; note whether jugular veins are patent. Look for jugular venous pulsations as described previously.

3 Obtain blood for the following:

a CBC

b Fibrinogen concentration

c Total protein concentration

d BLV status (bovine) and serology for equine influenza, viral arteritis, and herpesvirus

e Vitamin E (serum) and selenium concentrations if cardiomyopathy suspected

4 Take radiographs of the thorax and abdomen to establish whether there is respiratory disease, a magnet, or a penetrating foreign body.

5 Record an ECG when there is an arrhythmia to look for atrial premature depolarizations.

6 Perform an echocardiogram to examine the following:

a Right ventricular size and function

b Right atrium, for abnormal size or structures

c Tricuspid valve

d Pulmonary artery diameter

e Left atrial size

f Left ventricular size and function

g Pericardium

h Interventricular septal thickness and motion

7 Perform Doppler echocardiogram to look for:

a Tricuspid regurgitation

b Pulmonic regurgitation

c If tricuspid or pulmonic regurgitation detected, check for concurrent mitral and aortic regurgitation

8 Perform ultrasound examination of the cranial thorax and cranial mediastinum.

9 Jugular venous catheterization may be useful to determine right atrial (central venous), right ventricular, and pulmonary arterial pressures.

6.7 PAINFUL PERIPHERAL SWELLINGS

Close inspection of the skin and extremities of patients can reveal evidence of peripheral vascular or lymphatic system disease. These diseases can be manifested by diffuse swelling, localized swelling (papules, nodules, macules, or wheals), or subcutaneous edema of the extremities. Frequently there is necrosis, ulceration of the skin, and exudation as the disease progresses. Animals may be lame or dyspneic, have heat in the involved area, or exhibit a painful response to palpation of the area (Boxes 6-14 and 6-15), which helps to differentiate these conditions from nonpainful peripheral edema.

6.7.1 Approach to Diagnosis of PainfulPeripheral Swellings

1 Take history. Establish whether there is a history of a wound or trauma to the area or previous drainage; inquire about previous infections, particularly those referable to the respiratory system, in this animal or others; determine vaccination, deworming, and drug administration history.

2 Perform a physical examination. Determine vital signs. Note whether animal is febrile; examine extremities for wounds, dilated lymphatic channels, ulcers, focal swellings, and edema; determine the temperature and sensitivity of the swollen area; examine mucous membranes for color and presence of hemorrhages; perform a rectal examination and palpate aortic quadrifurcation in horses for vessel size, firmness, pain, fremitus, and strength of pulse; evaluate these vessels before and after exercise, if indicated; test saphenous refill by holding off the saphenous vein distally over the hock, stripping the vein proximally and releasing the pressure over the vein at the level of the hock.

3 Obtain blood for the following:

a CBC (includes examination of red blood cells, neutrophils, and eosinophils for inclusion bodies or morula and determination of platelet count)

b Fibrinogen concentration

c Total protein concentration

d Coombs' or direct immunofluorescence test

e Appropriate tests for equine ehrlichiosis (immunofluorescence assay), piroplasmosis (complement fixation), or viral arteritis (serum neutralization), if indicated

4 Take radiographs of swollen extremities, if appropriate.

5 Perform an ultrasound examination of the swelling, if appropriate.

6 Obtain Gram stain and bacterial and fungal culture of ulcerated area or exudate.

7 Perform a biopsy of granulomas and submit for histopathology and culture and sensitivity testing, if appropriate.

8 Analyze and culture fluid obtained from dilated lymphatic channels or localized edematous areas.

9 Analyze urine to look for hemoglobinuria or hema-turia.

10 Test feces for fecal occult blood.

6.8 ENLARGED LYMPH NODES

93

94

Diffuse or single lymph node enlargement occurs with infectious (bacterial, viral, fungal) conditions, neoplasia, and, rarely, immune-mediated causes in large animals (Boxes 6-16 and 6-17). Lymphadenopathy may cause obstruction to lymphatic drainage, leading to peripheral edema, pleural effusion, or ascites. The peripheral lymph nodes that are most readily accessible for examination are the submandibular (horses), superficial cervical (ruminants), and superficial inguinal (ruminants) lymph nodes. When there is generalized lymphadenopathy, internal lymph nodes may be enlarged, causing clinical signs such as dyspnea, esophageal obstruction, diarrhea, or other signs of organ dysfunction.

6.8.1 Box 6-16 Causes of Enlarged Lymph Nodes in Horses

6.8.1.1 COMMON CAUSES

Strangles

Lymphosarcoma

Upper respiratory infection

Corynebacterium pseudotuberculosis lymphadenitis

6.8.1.2 UNCOMMON CAUSES

- Ulcerative lymphangitis
- Epizootic lymphangitis
- Sporadic lymphangitis
- Glanders
- Granulomatous lymphadenitis
- Plasma cell myeloma
- Tuberculosis
- Hemolytic uremic-like syndrome

6.8.2 Box 6-17 Causes of Enlarged Lymph Nodes in Ruminants

6.8.2.1 COMMON CAUSES

- Caseous lymphadenitis (*Corynebacterium pseudotuberculosis*)
- Lymphosarcoma (including bovine leukosis virus)
- Abscess or cellulitis of area drained

6.8.2.2 UNCOMMON CAUSES

- Tuberculosis
- Sporadic bovine encephalomyelitis
- Malignant catarrhal fever

6.8.3 Approach to Diagnosis of Enlarged Lymph Nodes

1 Take history. Note especially history of weight loss, inappetence, depression, lethargy, or lymph node enlargement; inquire about previous illness or wounds; for cattle, determine whether there is a history of lymphosarcoma in the family or herd and whether the cow has a positive BLV test result; for sheep and goats, determine whether there is a history of *Corynebacterium pseudotuberculosis* abscesses in the flock or herd.

2 Perform physical examination. Determine vital signs. Examine peripheral lymph nodes or other swellings, perform a rectal examination to palpate accessible internal lymph nodes, and, when appropriate, examine the uterus in cattle; check mucous membranes for pallor or icterus; determine whether there is jugular venous distention or pulsations or whether there is evidence of pleural or pericardial effusion or ascites.

3 Obtain blood for the following:

a CBC to examine for anemia or leukemic changes; note inclusions, morula, or abnormal appearance of cells

b Serum chemistry profile to determine if there are signs of other organ dysfunction (e.g., gastrointestinal [hypoproteinemia], liver, or kidney)

4 Test feces for occult blood, if indicated.

5 Perform ultrasonographic examination of the lymph node or swelling.

6 Obtain lymph node or swelling aspirate and biopsy sample for culture and histopathologic examination.

7 Obtain a bone marrow sample for cytologic exam-ination.

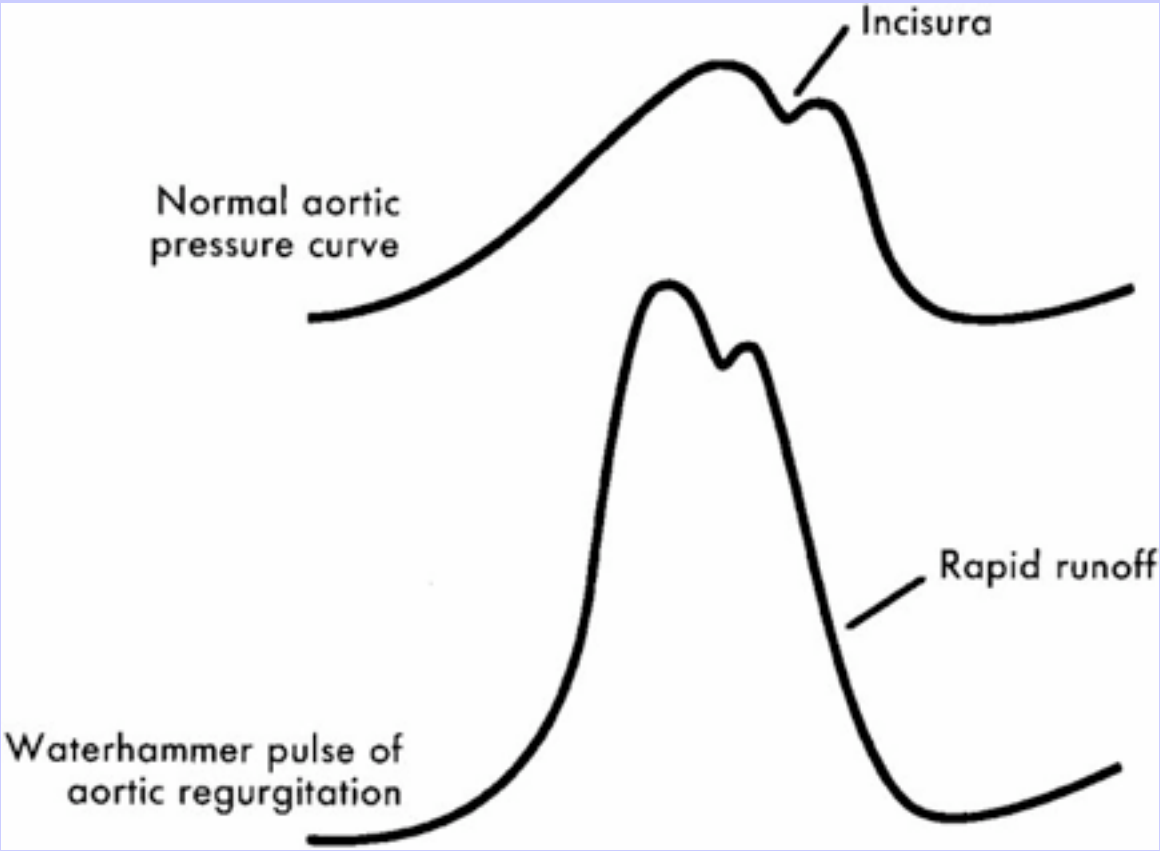
6.9 ABNORMAL PERIPHERAL PULSE

Palpation of the arterial pulse is an important aspect of the examination of the patient with cardiovascular disease. Arterial pulse strength and contour (how fast pressure rises and falls) are the objectives of the examination and are determined by the cardiac output, heart rate, and vascular impedance. The arterial pressure pulse begins with the opening of the aortic valve and ventricular ejection and rises rapidly in early systole. The pulse pressure reaches a peak then declines as ventricular ejection slows. During isovolumic relaxation (before AV valve opening), there is a transient reversal of flow in the arterial system, and an incisura or dicrotic notch (Fig. 6-6) is inscribed on the descending limb of the pressure curve. Following the incisura, there is a small positive wave that is attributed to elastic recoil of the aorta and the aortic valve and the summation of reflected waves from more distal arteries.[15] After the positive wave, the pulse pressure declines because there is peripheral runoff of blood in diastole. The incisura and secondary positive wave are not usually palpable. Palpation of peripheral arteries (facial, transverse facial, and digital arteries in the horse and median and coccygeal arteries in ruminants) normally reveals a smooth, rapid upstroke, a dome-shaped summit, and a downstroke that is slightly more prolonged than the upstroke.

Pressure values and pulse wave configurations are altered as the pressure waves are transmitted through the peripheral arterial tree. With increasing distance from the heart, the dicrotic notch and second positive wave disappear, the systolic pressure gets higher (loss of distensibility in the distal arteries and summation of reflected pulse waves from the distal vascular bed), and the diastolic pressure gets lower. The difference between the systolic

and diastolic pressure determines pulse pressure and can be evaluated by an impression of pulse strength. Pulse pressure increases as one moves to more peripheral arterial sites. The mean arterial pressure changes very little but decreases slightly as one moves downstream in the arterial system from the pressure source. Systolic blood pressure, as measured indirectly at the tail or on a limb, is higher than that measured in the ascending aorta. In smaller arterial beds (e.g., arteries of the ear), the pulse wave is gradually dampened and pulsatile characteristics are lost on the capillaries and small veins.

Fig. 6-6 Schematic illustration of the normal arterial pressure pulse. The incisura that occurs during the descending limb is caused by a transient reversal in flow during isovolumic relaxation. Compared with the normal arterial pressure pulse, the waterhammer pulse of aortic regurgitation builds rapidly and has a rapid runoff.



6.9.1 Mechanisms of Abnormal Peripheral Pulse

Hyperkinetic arterial pulses occur in patients with increased cardiac output (e.g., fever, exercise, excitement), increased stroke volume, or bradycardia (Boxes 6-18 and 6-19). It may also occur when there is rapid runoff of blood in the arterial system, as occurs with aortic valve regurgitation, patent ductus arteriosus, or aortic cardiac fistulas. In aortic valve regurgitation the rapidly rising, hyperdynamic pulse is caused by increased stroke volume

(regurgitated blood in the left ventricle), followed by a rapid runoff of pressure later in systole as a result of regurgitation (see Fig. 6-6).

Hypokinetic pulses are present in patients with diminished stroke volume caused by hypovolemia, left ventricular failure, or, rarely, in large animals, mitral or aortic valve stenosis.

Abnormal peripheral pulses are detected in patients with cardiac arrhythmias. With premature ventricular contractions (PVCs), the compensatory pause that occurs after the PVC allows a longer period of time for ventricular filling, which results in a greater end-diastolic volume, increased contractile force, and a stronger pulse in the beat that follows the PVC. The strength of the peripheral pulse is variable in arrhythmias such as atrial fibrillation because the irregular rhythm is associated with variable time for ventricular filling. Certain arrhythmias, particularly tachyarrhythmias, allow inadequate ventricular filling to generate a peripheral arterial pulse, and a pulse deficit is palpated.

6.9.2 Approach to Diagnosis of Abnormal Peripheral Pulse

1 Take history. Note changes in appetite, attitude, milk production, or ability to exercise; determine whether there have been signs of previous illness and duration and progression of the problem.

2 Perform a physical examination. Determine vital signs. Note whether there is a cardiac arrhythmia, murmur, or other evidence of heart disease (e.g., jugular venous distention or pulsation, edema). Palpate the pulse in multiple sites and bilaterally to rule out occlusive arterial disease; check patient's hydration.

3 Obtain blood for the following:

   a CBC; look for evidence of toxemia or anemia

   b Blood gases to determine acid-base balance

   c Electrolyte concentration, especially Ca and K

4 Record an ECG to characterize any arrhythmia.

5 Determine blood pressure. The site for indirect blood pressure measurement in the standing animal is the tail over the coccygeal artery; a limb can be used in a recumbent animal. Take the mean of several (minimum of three) readings in which the blood pressure cuff is gradually inflated and deflated at approximately 2 to 4 mm Hg/sec; values obtained should be corrected for the difference in height between the site measured and the heart, which is considered to be at the level of the shoulder; the difference in height (centimeters) between the heart and the site of pressure measurement is multiplied by 0.77 (constant used to convert centimeters of blood to millimeters of mercury). In standing horses, approximately 27 mm Hg is added to the indirectly measured coccygeal artery pressure to give the corrected value[17]; no correction factor is needed if the measurement is made in a recumbent animal. An appropriately sized blood pressure cuff is considered to be one fourth of the tail circumference[18]; in horses a 4.5- to 5.6-cm cuff has been recommended for electronic oscillometric devices, and a 10.6-cm cuff for ultrasonic flowmeters.[17] Values for normal horses by blood flow detection methods are 79/49 to 145/106 mm Hg (uncorrected for the height of the tail).[16]

6 Blood pressure can be evaluated by Doppler scan, or measurements can be recorded by direct cardiac catheterization (see Chapter 30).

7 Perform an echocardiogram to evaluate size of chambers, myocardial function, presence of valvular or pericardial disease, or congenital defects.

7 Chapter 7 Alterations in Alimentary and Hepatic Function

Bradford P. Smith

K. Gary Magdesian

7.1 DIARRHEA

K. GARY MAGDESIAN,

BRADFORD P. SMITH,

Diarrhea, is defined as an increase in the frequency, fluidity, or volume of bowel movements. Diarrhea may be a sign of a primary bowel disease or a nonspecific response to sepsis, toxemia, or disease of another organ system.

Under normal circumstances a large volume of essentially isotonic fluid enters the proximal bowel daily. Most of this fluid is resorbed, and only a small percentage is passed with the feces. The fluid comes from dietary intake and from endogenous secretions of the upper digestive tract. The total daily volume exchanged exceeds that of the animal's total extracellular fluid volume. Normally absorption just exceeds secretion; therefore very small changes in rate of absorption or secretion can result in diarrhea. In the horse most water resorption occurs in the cecum and large colon, and diarrhea in the horse (other than neonates) usually involves some abnormality in the lumen or wall of the large bowel.

Normal fecal color is tan, brown, or greenish, depending on diet. The adult horse normally produces 11 to 13 kg of fecal material per day (20 to 28 g/kg of body weight per day) while on a diet of grass hay and 3 lb of oats.[1] Fecal output was as high as 20 kg/day in horses fed a mixture of alfalfa and orchard grass ad libitum.[2] Horses with chronic watery diarrhea can produce up to 214 g/kg of body weight per day,[1] which is over 90 L of diarrhea in a 450-kg horse. Cattle normally produce 15 to 28 kg of feces per day with a water content of about 75% to 85% on a diet of grass hay.[3] Fluidity of cattle feces can increase markedly in animals on lush green feed. Sheep and goat feces contain only 50% to 60% water.[3] Fluid feces in the cow and unformed feces in the horse, goat, and sheep are very nonspecific signs that often accompany sepsis or illness other than a primary gastrointestinal disease.

Animals with chronic diarrhea rarely develop severe dehydration because they compensate for increased fecal water losses by increasing water consumption by an equivalent amount. Normal water consumption in the horse on a hay diet in a mild ambient temperature environment is about 24 to 30 L/day, whereas cattle consume 30 to 60 L/day based on 10 kg of dry matter feed intake. Water and feed intake do not increase linearly with increasing body size, but by multiplying body weight in kilograms to the 0.75th power ($BW^{0.75}_{kg}$) by a base factor (about 200 mL for water). Thus a 500-kg horse requires 21 L of water. The effect of temperature on water intake is dramatic and is not linear; as ambient temperatures rise close to 37° C (98° F), water intake per kilogram of dry matter increases much more rapidly than at lower temperatures. Exercise and loss through sweat, particularly in the horse, can dramatically increase salt and water requirements.

7.1.1 Mechanisms of Diarrhea (Box 7-1)

The following six major mechanisms produce diarrhea:

- Decreased or damaged absorptive surface area (malabsorption)
- Increased numbers of osmotically active particles within the intestinal lumen
- Increased volume of secretion of solutes and water
- Abnormal intestinal motility resulting in decreased transit time, as with systemic inflammatory response syndrome (SIRS)
- Increased blood-to-lumen pressure as in heart failure or acute or chronic inflammatory bowel diseases
- Gastrointestinal inflammation, as occurs with peritonitis

The common net result is an increase in fecal water.

Decreased surface area, is mainly a result of villus blunting (atrophy) and/or microvillus damage in the small intestine, which lead to malabsorption. Both occur to some degree with most enteric diseases, and regeneration of surface area from crypt cells with healing is accompanied by a gradual decrease in volume of diarrhea. Diseases in which this is a major mechanism include neonatal diseases such as rotavirus and coronavirus enteric disease,[4] cryptosporidiosis, acute inflammatory disease such as salmonellosis, and chronic diseases such as Johne's disease and other granulomatous bowel diseases. The finding of villus atrophy is so nonspecific that it is not diagnostic in itself. It can also occur in advanced cases of secondary copper deficiency (molybdenosis) with diarrhea. Loss of villus epithelial cells can result in maldigestion because these cells produce important enzymes such as lactase. Many neonates with enteritis develop temporary lactose intolerance as a result, especially with rotaviral and clostridial infections.

7.1.1.1

Box 7-1 Mechanisms of Diarrhea

Malabsorption (villus atrophy)

Osmotic overload

Secretory

Abnormal motility

Increased blood-to-lumen hydraulic pressure

Inflammation

Decreased transit time

Inflammation, can be accompanied by increased mucus production and increases in size of membrane pores, through which tissue fluids and serum proteins leak into the lumen. This is associated with increased capillary

and lymphatic hydraulic pressures. Whether acute *(Salmonella)*, or chronic (Johne's), inflammatory bowel diseases are protein-losing enteropathies. Low plasma protein concentrations, particularly low albumin, are often found (unless hypovolemia and hemoconcentration are present). Bowel inflammation often results in transudation and exudation of serum proteins, blood, and/or mucus, resulting in dysentery (bloody diarrhea). In addition to salmonellosis, dysentery may also commonly be seen with enterotoxemia caused by *Clostridium perfringens*, type A, B, or C, *Clostridium difficile, Lawsonia intracellularis*,[5] attaching effacing *Escherichia coli, Campylobacter jejuni*, coccidiosis, malignant catarrhal fever (MCF), arsenic toxicity, and oak toxicity. Inflammation results in malabsorption, maldigestion, osmotic effects, and, in acute disease, changes in intestinal motility. Because most water absorption in the horse occurs in the cecum and colon, inflammatory typhlitis and colitis are the major causes of diarrhea in the horse (Boxes 7-2 and 7-3). The neonatal foal commonly develops small intestinal enteritis.

7.1.1.2

Box 7-2 Causes of Diarrhea in Horses (Except Neonates; see Chapter 19 for Neonates)

7.1.1.2.1

COMMON CAUSES

Colitis or typhlitis

Salmonellosis

Enteritis, unknown cause

Potomac fever (equine monocytic ehrlichiosis)

Endotoxemia or gram-negative sepsis

Overfeeding or sudden change in diet

Clostridium difficile,

7.1.1.2.2

LESS COMMON CAUSES

Eosinophilic gastroenteritis

Renal failure, uremia

Necrotizing enterocolitis

Heart failure

Enterotoxemia *(Clostridium perfringens*, mainly type A)

Lawsonia intracellularis, (mainly foals and weanlings), proliferative enteropathy

Intestinal lymphosarcoma

Cathartics or laxatives

Parasympathomimetics

Chronic granulomatous bowel disease

Proximal enteritis

Peritonitis

Intussusception

Sand, gravel, or enterolith in gut lumen

Gut stenosis

Antibiotic use

Rhodococcus (Corynebacterium) equi, gut infection (mainly foals)

Cryptosporidiosis (mainly foals)

Giardiasis (mainly foals)

Toxins or poisonous plants (see Box 7-3)

7.1.1.2.3 UNCOMMON CAUSES

Hepatic failure

Cholelithiasis

Vascular aneurysm

Combined immunodeficiency

Agammaglobulinemia

Lactose intolerance (mainly foals)

Campylobacter jejuni, (mainly foals)

Colorectal polyps

Anaphylaxis

Vitamin A deficiency

Tularemia

Snake bite, insect or spider sting or bite

Histoplasmosis

Hydroallantois

Hyperlipidemia

Internal abdominal abscess

Pheochromocytoma

Viral arteritis

Besnoitiosis (globidiosis) (exotic)

Irritation of the bowel with a foreign body such as sand may result in either low-grade recurrent colic or diarrhea. Weight loss may also be evident with a large amount of sand. Sand accumulation in the large bowel of the horse may be suspected when there is evidence of a significant amount of sand in the feces or when sand is auscultable

with a stethoscope over the ventral abdomen. Irritation probably causes diarrhea through creation of an inflammatory response and altered motility.

Osmotic diarrhea, results from any disease causing maldigestion and/or malabsorption. Any osmotically active solute can produce diarrhea in normal animals if given in quantities sufficient to surpass the intestinal capacity for digestion or absorption. Disaccharides are natural examples. Osmotic cathartics such as dioctyl sodium sulfosuccinate (DSS) hold water in the intestine and act as fecal softeners. Magnesium phosphates and sulfates and other divalent and trivalent cations and anions are poorly absorbed and thus are effective laxatives and cathartics.

Osmotic diarrhea can be associated with ingestion of osmotically active poorly absorbed solutes, overloading of the intestine with carbohydrates or lipids beyond the amount that can be digested and absorbed, sudden dietary changes resulting in marked shifts in gut flora and resulting bacterial action on ingested substrate (e.g., grain overload), or bowel disease in which surface area is diminished or digestion interfered with in some manner. Lactase deficiency, secondary to rotavirus or *C. difficile*, infections, may result in osmotic diarrhea in foals.[6] This results in increased concentration of undigested and/or unabsorbed nutrients entering the lower bowel, increased bacterial fermentation, and an increase in the concentration of osmotically active particles. Unfavorable electrochemical gradients prevent resorption of water. Mucosal digestive enzyme levels are often decreased with any disease involving the small intestine, resulting in maldigestion. When osmotic diarrhea is suspected in mature animals, dietary modification to basic roughage should be tried as part of the nonspecific therapy. Sodium and potassium are normally present in roughly equal amounts in feces and (with a little ammonium) make up the vast majority of cations in the feces. Concentrations of sodium and potassium in feces and osmotically active nonelectrolytes influence fecal water. In general, osmotic diarrheas diminish when the animal is fasted. When the offending substance is reintroduced, diarrhea occurs.

Pimela poisoning (St. George disease) (exotic)

Grass sickness (exotic)

Secretory diarrheas, are most important in neonates[4] (enteropathogenic *E. coli*), but many strains of *Salmonella*, associated with colitis in large animals may produce enterotoxins that stimulate secretion. Enterotoxins act by stimulating cyclic adenosine monophosphate (AMP) or other intracellular messengers to promote secretion of chloride, sodium, and other electrolytes into the gut lumen. Water is carried with these electrolytes and osmotically retained. The hallmark of secretory diarrheas is the large volume of feces produced.

Examples of secretory diarrheas are enterotoxigenic *E. coli*, and many strains of *Salmonella*, and *C. perfringens. Salmonella*, and other invasive organisms produce inflammation that may induce prostaglandin-mediated secretion as well. Secretion may occur with viral diarrhea by a different mechanism, as damaged mature (absorbing) villus cells are replaced by immature (secreting) crypt cells.[7] A good example is rotavirus.

Decreased intestinal transit time, associated with increased peristalsis and/or decreased segmentation appears to occur in many bowel diseases because of bowel irritation. *Peritonitis*, is a major cause of bowel inflammation and should always be explored as a contributing cause of diarrhea, especially when fecal output volume is scant. Abnormal motor patterns have been demonstrated to occur with many infectious diarrheas and may be a bowel response to irritation and/or increased intraluminal volume. Elimination of gut contents thus appears to be a normal gut defense mechanism against infection and probably should not be pharmacologically alleviated in acute infectious diarrheas. Primary motility disorders of animals are not well recognized; diarrhea associated with nervous or excited animals may be the best example of this type. In general, fecal volume associated with motility disorders is not great.

Increased hydraulic pressures, from the blood to the lumen also decrease net absorption of fluid. These can result from decreased oncotic pressure (hypoalbuminemia), increased capillary hydrostatic pressure (heart failure or portal hypertension as with liver disease), or decreased lymphatic drainage associated with inflamed or blocked lymph vessels or nodes (lymphosarcoma). These mechanisms are most commonly associated with chronic diarrhea, but acute inflammation can also result in diarrhea associated with this mechanism.

Two or more of these mechanisms are probably at work in most diarrheal diseases. Therapy of diarrhea is therefore nonspecific, except when the actual causative agent can be identified. Diagnosis of a specific causative agent is most important when diarrhea is caused by an infectious agent, so that appropriate therapeutic steps can be taken before chronicity develops, spread of disease can be prevented, and an accurate prognosis can be made.

In mature horses, small intestinal diseases such as granulomatous bowel disease or duodenitis or proximal jejunitis (anterior enteritis) may not be associated with diarrhea, and diseases of the stomach almost never cause diarrhea. Most significant diarrheal disease in adult horses involves the large colon because this is the principal site of water absorption. The exception to this is the neonatal foal, in which primarily small intestinal diseases such as rotavirus infection and cryptosporidiosis may cause severe diarrhea.

The frequency of defecation is usually increased when diarrhea is present, and defecation is most frequent when the colon or rectum is irritated. When these areas are involved, *tenesmus*, (straining) may result. Tenesmus can also occur with hepatic failure in ruminants and in horses and ruminants with rectal tears or strictures, vaginitis, retained placenta, dystocia, intussusception, urolithiasis, rabies, and diseases involving the nervous system when there is retention of feces or urine. Severe rectal irritation can lead to straining and rectal prolapse.

98

99

In ruminants, abnormalities such as grain overload (toxic indigestion) resulting in ruminal osmotic changes can produce diarrhea, as can changes in abomasal pH such as occur with type II ostertagiasis. Diarrhea in ruminants is frequently caused by forestomach problems (Boxes 7-4 and 7-5). The colon and remainder of the distal bowel are involved in diseases such as salmonellosis. Gram-negative infections and resulting endotoxemia, found in conditions such as coliform mastitis and septic metritis, are relatively common causes of nonspecific diarrhea. Foals with septicemia also commonly develop nonspecific diarrhea associated with SIRS. Diarrhea may be (1) a manifestation of a primary disease (bovine viral diarrhea [BVD]; Johne's disease; *C. difficile*), (2) one of the signs of a generalized disease (MCF, uremia), or (3) secondary to toxemia (coliform mastitis, septic metritis, septicemia).

7.1.2 Nonspecific Fluid Therapy for Diarrhea

Dehydration, electrolyte losses, and acid-base abnormalities can occur rapidly when diarrhea is present. Symptomatic treatment to correct these problems is an important component of nonspecific therapy in animals with diarrhea. Very often the cause of diarrhea remains undetermined, yet symptomatic correction of hypovolemia, dehydration, and acid-base and electrolyte abnormalities can result in a return to normal function, particularly if the diarrhea is acute and severe. Fluids and electrolytes can be given orally or parenterally. Oral fluids can be given rapidly and inexpensively. Oral fluids should be isotonic or hypotonic. The degree of dehydration should be estimated as a percentage of body weight. Mild dehydration is usually considered less than 5%; moderate, 5% to 8%; and severe, over 8%. Thus a severely dehydrated 450-kg patient with an estimated 10% dehydration (weakness, cold extremities, sunken eyes, decreased urine output, decreased elastic skin rebound, weak pulse, rapid heart rate) requires 45 L of fluids.

The best way to determine electrolyte needs is to take a plasma or serum sample before initiating fluid therapy. Electrolyte requirements can be estimated; with diarrhea, mixed water and electrolyte losses occur, so that sodium-containing fluids are usually required to replace lost sodium and improve blood volume (see also Fluid and Electrolyte Balance, Chapter 22). Unless the acid-base status can be measured, the safest sodium-containing fluids are balanced polyionic fluids such as Ringer's or lactated Ringer's solution. Normal saline is a satisfactory alternative in most cases, but the relatively high concentration of chloride ions in saline can aggravate a preexisting metabolic acidosis unless hypochloremia is also present. In calves with severe metabolic acidosis, use of fluids containing sodium bicarbonate is indicated. In horses, it is best not to include gram quantities of sodium bicarbonate in fluids unless there is good evidence that a severe metabolic, strong ion acidosis exists (such as hyperchloremia). Flow rates for administering isotonic intravenous fluids should be kept as slow as possible to avoid fluid overload, pulmonary edema, and excessive diuresis. When the patient is shocky, flow rates close to 20 mL/kg/hr or faster may be required for administration of isotonic crystalloid fluids, but in general rates below 10 mL/kg/hr are desirable, especially once hypovolemic shock has been addressed. Hypertonic saline (7% NaCl) may be given rapidly intravenously at a dose of 4 to 5 mL/kg. When a colloid fluid is required to combat low plasma protein levels, hetastarch can be used. It is available as 6% hetastarch in lactated Ringer's or normal saline. See Neonatal Diarrhea, Chapter 20, Fluid and Electrolyte Balance, Chapter 22, and Fluid Therapy, Chapter 44, for more details on fluids and acid-base balance.

Trichothecene (T-2 toxin)

Plant toxins

Oak (acorn poisoning)

Senna occidentalis, (coffee weed)

Selenium accumulators

Slaframine (blackpatch diseased legumes, slobber factor)

Mycotoxicoses

Helenium (sneezeweed, bitterweed)

Solanum (nightshade)

Pyrrolizidine alkaloid (*Senecio, Crotalaria, Amsinckia*, species)

Brassica (mustards, crucifers, cress)

Oleander poisoning

Japanese yew *(Taxus cuspidata)*, poisoning

Whitehead *(Sphenosciadium capitellatum)*,

Pokeweed *(Phytolacca americana L)*,

Mushroom

Inkweed *(Drymaria pachyphylla)*,

Tung tree (aleurites)

Chinese tallow tree

Kalanchoe (crassulaceae)

Fungal toxicity

Sesbania (rattlebox)

Gutierrezia (broomweed, snakeweed)

Hypericum (St. John's wort; Klamath weed) poisoning

Agrostemma githago, (corn cockle) poisoning

7.1.3

Approach to Diagnosis of Diarrhea in the Horse (for Neonates, see Chapter 19)

1 Take history. Especially note change in diet, deworming program, housing and management, and whether diarrhea is acute or chronic. Note appetite, whether animal is drinking an adequate volume of water, and whether salt is available. Note whether it is a single or multiple case, if there are intercurrent diseases, or if other medications or exposure to toxins is involved. Most antimicrobials have been associated with diarrhea in horses, but especially lincomycin, tetracyclines, and erythromycin. Antimicrobials should be discontinued if diarrhea develops during administration. Most bacterial and protozoal agents rely on altered intestinal microflora to proliferate in the gut and cause diarrhea. Note whether nonsteroidal antiinflammatory agents were used before the development of diarrhea. Many causes of diarrhea can be eliminated from consideration on the basis of history. Find out about housing and whether animals have access to pasture, have access to natural water sources, or are stall confined.

2 Perform physical examination. Take vital signs (often normal in chronic cases). Perform rectal examination unless an infectious contagious agent is suspected. Note weight loss. Systemic signs of toxemia, SIRS, hypovolemia, and dehydration often accompany acute colitis, salmonellosis, equine monocytic ehrlichiosis (Potomac fever), clostridiosis, and many other acute diseases.

3 Examine feces. Perform gross inspection; note whether blood or fibrin is present (see list of causes of dysentery).

a Perform microscopic examination for ova and protozoa, especially for chronic cases. Perform Gram stain of feces. A predominance of gram-positive rods may indicate an anaerobic overgrowth such as occurs with *C. difficile*, infections.

b Perform multiple cultures for *Salmonella, C. difficile*,[8] and *C. perfringens*, if onset is acute, if animal is febrile, or if feces contain fibrin and mucus. A commercial polymerase chain reaction (PCR) test can be used as an aid to evaluate for the presence of salmonellosis.[9] An evaluation for *C. difficile*, and for *C. perfringens*, should be made if the diarrhea is temporally associated with antibiotic administration. Cultures for *C. difficile*, should be performed on selective media (cycloserine-cefoxitin-fructose agar). Recently *Brachyspira pilosicoli*, has been isolated from the feces of weanlings with chronic diarrhea.[10] This warrants further investigation as a cause of diarrhea and failure to thrive in young horses.

c Several enzyme-linked immunosorbent assay (ELISA) kits are available for identification of toxins A (enterotoxin) and B (cytotoxin) of *C. difficile*, in feces. A stool cytotoxin cell culture is available for toxin B.[11,12] Toxin B cell culture testing is considered the gold standard.[13]

d Isolates of *C. perfringens*, should be examined for the ability to produce beta 2–toxin, as these strains are most often associated with gastrointestinal disease.[14] Beta 2–toxin is found by PCR. In addition, a commercial fecal ELISA is now available for detection of alpha-toxin, beta-toxin, and epsilon-toxin at the California Animal Health and Food Safety Laboratory (San Bernardino). This allows diagnosis of *C. perfringens*, types A, B, C, and D.

e Fecal occult blood (if positive, see list of causes of melena and blood in feces, pp. 106 and 107).

f Fecal osmolality, sodium, and potassium concentrations (optional). Electrolyte concentration in feces is roughly twice the sodium plus potassium. When this value is much lower than the measured osmolality of the feces, the difference is an osmolar gap caused by osmotically active nonelectrolytes, and osmotic diarrhea is confirmed.

g Check for sand by placing some feces in a bucket of water, mixing thoroughly, and decanting the water. If a radiographic unit with the appropriate power capability is available, abdominal radiographs can be taken to detect the presence and amount of sand. Ultrasound of the ventral abdomen can be used to diagnose the presence of sand, although this requires considerable expertise.

h A PCR test for feces is available at University of Minnesota Diagnostic Lab and the University of California Molecular Laboratory for detection of *L. intracellularis*, organisms in weanlings and yearlings with diarrhea, weight loss, general malaise, and hypoalbuminemia.[15] Also see serum test described later.

i *Rhodococcus equi*, can cause diarrhea in 3-week- to 6-month-old foals. Diagnostic tests include cultures of transtracheal aspirates, abdominal fluid cytology and culture, and abdominal ultrasonography. Fecal PCR techniques are available on a limited basis.[16]

j If all other cultures are negative and an infectious cause of diarrhea is suspected, the feces should be cultured for *Aeromonas*, species and *C. perfringens*.,[17] A positive culture for *C. perfringens*, should be coupled with an evaluation for the presence of toxins or toxin genes to confirm pathogenicity, as the organism may be cultured as part of the normal flora. Recent reports implicate a novel beta 2–toxin—producing *C. perfringens*, as a potential pathogen in colitis of adult horses.[18] Commercial toxin ELISA tests are now available for alpha-, beta-, and epsilon-toxins (California Animal Health and Food Safety Laboratory, San Bernardino).

4 Obtain blood for the following database:

a Complete blood count (CBC; includes fibrinogen and plasma proteins). Increased fibrinogen indicates inflammation. Decreased proteins indicate protein-losing enteropathy. Thrombocytopenia may indicate a coagulopathy. Neutropenia with or without a toxic, left shift (immature neutrophilia) is often present with infectious and inflammatory causes of acute colitis, indicating SIRS. Elevations in packed cell volume (PCV) and red cell mass are often present, indicating hemoconcentration and/or splenic contraction in horses.

b Acid-base values if condition is acute and dehydrated or toxic. Although acid-base values are not of much use diagnostically in terms of etiology, they allow for initiation of proper nonspecific supportive therapy.

5 Test serum for the following:

a Electrolytes (Na, K, Cl) (nonspecific).

b Serum creatinine and blood urea nitrogen (BUN)—prerenal azotemia is common as a result of dehydration; check again after rehydration. Serum chemistries should be evaluated for liver and other organ disease.

c Albumin and globulin values; hypoalbuminemia is seen with chronic protein-losing enteropathies such as granulomatous bowel disease, with phenylbutazone toxicity (right dorsal colitis), and with acute colitis conditions.

d Specific immunoglobulin (Ig) A, IgM, and IgG levels; immunodeficient individuals may have chronic diarrhea. Elevated globulins may indicate the presence of chronic disease.

e Paired sera for *Neorickettsia risticii*, titer following acute diarrhea with fever. PCR techniques are available to identify the agent in whole blood samples and feces.

f Immunoperoxidase monolayer assay and an immunofluorescence assay (IFA) for *L. intracellularis*, can be done, particularly in weanlings and yearlings. Fecal PCR analyses are now available.

g Clotting times (prothrombin time [PT] and partial thromboplastin time [PTT] or activated clotting time [ACT]) should be monitored as indicators of coagulopathies such as disseminated intravascular coagulation (DIC). Antithrombin III levels can be monitored for the risk of thromboses.

6 Perform paracentesis, especially if signs of colic are present. Evaluate cytology, protein, and fibrinogen values in chronic cases to rule out peritonitis, tumors, and mesenteric abscess.

7 Perform function and absorption tests in chronic diarrhea cases, especially when weight loss is present.

a Oral glucose or xylose small intestine absorption tests (see Chapter 32) for chronic cases, particularly if a high index of suspicion exists because of hypoalbuminemia. If tests indicate malabsorption, either biopsy the gut (or rectum) or assess response to treatment for 60 days following larvicidal anthelmintic dose.

b Perform liver function tests such as sodium sulfobromophthalein (BSP) half-time or serum bile acid concentrations if liver involvement is suspected as a result of elevated liver enzyme levels and/or hypoalbuminemia. Liver enzymes are elevated in many cases of enterocolitis and in these cases do not necessarily indicate primary liver disease (see Chapter 33).

8 Examine tissue.

a Rectal or intestinal biopsy for microscopic examination and fluorescent antibody for immune-mediated diseases (also culture for *Salmonella*). Rectal histopathology is particularly useful in horses with hypoalbuminemia or weight loss.[19]

b Detection of *C. perfringens*, beta 2–toxin from types A or C by immunohistochemistry of gut mucosa is diagnostic on biopsy or postmortem specimens.[20]

c Liver biopsy if indication of involvement in chronic cases.

9 Toxicology.

a Blood lead, liver lead, and liver arsenic concentrations can be measured if toxicity is suspected.[21]

b High-pressure liquid chromatography or gas chromatography-mass spectrometry can be used to detect cantharidin (blister beetle toxin) in urine or gastrointestinal contents.[22]

c Urine and gastrointestinal contents can be evaluated for the presence of oleandrin using thin layer chromatography. Oleander toxicity should be suspected in animals with diarrhea, colic, arrhythmias, and renal disease.[23]

101

102

10 Evaluate response to treatment with undiagnosed *chronic*, diarrhea.

a Alter diet to simple grass hay. Alternatively, a pelleted complete diet can be tried, especially if right dorsal colitis is suspected. Psyllium mucilloid, at 4 oz, and 1 to 2 cups of corn oil can be added to the daily diets of horses with right dorsal colitis.[24,25]

b Stop nonsteroidal drugs such as phenylbutazone if toxicity is possible cause.

c If no protozoa are seen in fecal sample, attempt transfaunation with colon or cecum contents from normal animal (if not available, use feces).

d Attempt to classify into type by rectal biopsy; many changes are nonspecific.

(1) Marked fibrosis and inflammatory changes point to a poor prognosis. Administer potentiated sulfas (5 mg/kg trimethoprim tid is therapeutic dose) and iodochlorhydroxyquin (Rheaform 10 g/450 kg horse/day) for 2 weeks.

(2) Mononuclear cell infiltrate. Administer 20 to 30 mg dexamethasone (Azium) per day, tapering down to 10 mg in 1 week; if response is favorable, continue with 600 to 800 mg prednisolone PO per day, taper over 2 months.

(3) Eosinophilic infiltrate. Administer larvicidal anthelminthic dose of fenbendazole plus corticosteroids as above.

e Transfusion with plasma (1 to 2 mL/kg) in young horses 2 to 12 months of age that may need some additional serum factors. Synthetic colloids, such as hetastarch, can be used in animals with reduced colloid osmotic pressure (hypoalbuminemia), especially if edema is present. Hetastarch has been used at 10 mL/kg.[26]

f Horses with Potomac fever often respond favorably to systemic treatment with tetracycline.

g Metronidazole (15 mg/kg PO tid) can be used empirically, especially if an anaerobic overgrowth is suspected, or when the diarrhea is secondary to antibiotic use.[27]

7.1.4 Approach to Diagnosis of Diarrhea in Ruminants (for Neonates, see Chapter 20)

1 Take history. Especially note diet, appetite, previous deworming and vaccinations, and whether it is an individual or herd problem. In animals less than 1 year of age coccidia, *Ostertagia*, or other helminths should be strongly considered. Determine if onset is acute or chronic. If chronic, first consider diseases such as parasitism, Johne's disease, copper deficiency (molybdenosis), selenium deficiency, liver failure,

and other diseases of individual cows such as bovine leukosis virus (BLV), amyloidosis, heart failure, or uremia.

2 Perform physical examination. Especially note weight loss, fever, systemic signs, rumen activity, and oral lesions. Perform rectal examination. In most acute-onset diseases, vital signs are abnormal, and systemic involvement or oral lesions (especially with BVD) may be obvious.

3 Examine feces.

- a Gross inspection
- b Microscopic examination for ova and parasites
- c Culture for *Salmonella*, if animal is febrile or feces appear inflammatory (fibrin or mucus)
- d Check for fecal occult blood
- e Culture of *Mycobacterium avium*, subsp. *paratuberculosis*, if weight loss is a problem (especially if a herd problem in animals over 2 years of age)

4 Take rectal scrapings of mucus.

- a Make thin smear on slide for acid-fast staining for Johne's disease. Examine under oil immersion lens.

5 Obtain blood for the following:

- a Plasma proteins
- b Fibrinogen
- c In acute cases, electrolytes and acid-base status
- d If a herd problem, copper and selenium status

6 Test serum for the following:

- a BUN
- b Liver enzymes (γ-glutamyltransferase [GGT] and sorbitol dehydrogenase [SDH])
- c Albumin and globulin values
- d Agar gel immunodiffusion (AGID) for BLV (single animals); request gp51 and p24 antibody status
- e If Johne's disease is suspected, perform ELISA test

7 Perform paracentesis. Paracentesis rules out gross peritonitis, but many false-negatives are possible as a result of focal or fibrinous peritonitis.

8 Perform urinalysis for protein to rule out consideration of amyloidosis or other multisystemic immune-mediated disease. Because ruminants normally have a urine pH of 8 or higher, most dipstick tests will give a trace or a 1+ positive reading for urine protein even when the animal's urine is normal.

9 Examine tissue.

a Rectal, intestinal, or mesenteric lymph node biopsy for acid-fast stain for Johne's disease, for culture for *Salmonella*, and for presence of lymphosarcoma

10 Perform feed analysis (herd problem only).

a Copper, molybdenum, and selenium

b Toxins suspected (e.g., mercury, arsenic)

11 Tap abomasum for increased pH; rule out type II ostertagiasis

12 Perform necropsy (herd problem only).

a Pick severely affected individual to examine thoroughly

7.2 COLIC

K. GARY MAGDESIAN,

BRADFORD P. SMITH,

Colic, is defined as the manifestation of visceral abdominal pain. Colic may be the result of nongastrointestinal pain, such as urinary tract obstruction (Boxes 7-6 and 7-7). This section discusses colic of gastrointestinal origin. Pain may be acute, chronic, or recurrent. Gas distention or recognizable organic problems such as displacements are most frequently associated with acute colic. Five basic causes in large animals are as follows:

- Distention of gut with fluid, gas, or ingesta
- Pulling on the root of the mesentery (mesenteric tension)
- Ischemia or infarction
- Deep ulcers in the stomach or bowel
- Peritoneal pain (peritonitis)

The horse exhibits colic frequently, because it appears to have a low threshold for pain and is frequently beset by minor digestive disturbances that result in distended bowel. Signs of colic in the horse include restlessness, lying down and getting up, groaning, grunting, rolling, sweating, kicking at the abdomen, or suddenly dropping to the ground in pain. Anorexia and depression often accompany these signs. Horses may develop tachycardia with weak pulse quality and prolonged capillary refill time, cold extremities, and bright red (vasodilatory phase) followed by dark (vasoconstrictive phase or low cardiac output state) mucous membranes if the problem is severe and affects cardiovascular integrity.

7.2.1

Box 7-6 Gastrointestinal Causes of Colic in Horses

7.2.1.1

COMMON CAUSES

Accumulation of intestinal, cecal, or colonic gas

Hypermotility and intestinal spasms

Feed impaction, constipation

Meconium impaction (newborn)

Gastric ulcers (foal)

7.2.1.2

LESS COMMON CAUSES

Thromboembolism

Intestinal foreign body (sand; enterolith; phytobezoar)

Volvulus of small intestine

Pedunculated lipoma with bowel strangulation

Hernia, inguinal, epiploic, umbilical, diaphragmatic

Nephrosplenic ligament bowel entrapment

Ascarid impaction

Massive strongyle infection

Gastric dilation

Anterior enteritis (duodenitis or proximal jejunitis)

Enteritis, impending or active

Peritonitis

Parasympathomimetic drugs

Irritant cathartics

Necrotizing enterocolitis

Psychogenic colic

Rectal tear

Volvulus or displacement of large bowel

Rupture of stomach or intestine

Ileus

Intussusception

7.2.1.3 UNCOMMON CAUSES

Abdominal adhesions

Intramural hematomas of stomach or intestine

Stenosis or stricture of bowel lumen

Botulism

Tetanus

Potomac fever

Exhaustion

Anaphylaxis

Rhodococcus equi (Corynebacterium), gut abscesses

Cribbing or wind sucking

Abdominal fibroma

Segmental ischemic necrosis following mesocolic tearing

Equine viral arteritis

Anthrax with bleeding

Malignant edema (*Clostridium*, species)

Malignant mesothelioma

Gastric or intestinal tumor

Atropine

Vitamin K_3 deficiency (moldy sweet clover)

Grass sickness (exotic)

7.2.2

Box 7-7 Causes of Colic in Ruminants

7.2.2.1

COMMON CAUSES

Increased intestinal gas

Intussusception

Torsion or volvulus of the mesenteric root

Peritonitis

Intestinal foreign body or obstruction

Urolithiasis

Ruptured bladder

Acute pyelonephritis

Abomasal torsion

Abomasal ulcer

Cecal dilation or volvulus

Severe bloat

7.2.2.2 LESS COMMON CAUSES

Cystitis or urinary tract disease

Abomasal bloat (neonates)

Uterine torsion or rupture

Hernia

Parturition, impending

Hypermotility and spasms of gut

Feed impaction

Right displaced abomasums

Acute traumatic reticulitis, abomasitis, or duodenitis

Acute liver disease

Vagal indigestion

Atresia coli (neonates)

7.2.2.3 UNCOMMON CAUSES

Rabies

Rectal tear

Rectal prolapse

Grain overload

Water intoxication

Winter dysentery

Ovarian abscess

Fat necrosis

Cholelithiasis

Intestinal adhesions

Enterotoxemia

Ileus

Intestinal strangulation

Inversion of uterine horn

Malignant edema

Malignant mesothelioma

Ruptured uterine artery

Intestinal neoplasia

Aortic, iliac, or femoral thrombosis

Anaphylaxis

Renal cysts

Ruptured prepubic tendon

Vaginal laceration

Torsion of descending colon

Rinderpest (exotic)

7.2.2.4 TOXINS

Plant poisonings (many of those that cause diarrhea also produce colic; see plant toxins listed under Diarrhea)

Evidence of shock is usually present only when the disease condition is severe and involves infarctive disease (volvulus, torsion, thromboembolism) or advanced visceral distention (extreme flatulence, impaction, or dilation). Foreign bodies such as sand or enteroliths in the large colon may result in *low-grade recurrent colic*., When an enterolith is passed into the transverse colon where it obstructs the bowel, *signs of complete obstruction*, and acute colic ensue. These signs are manifestations of visceral pain, mediated by the sympathetic nervous system. External palpation and pushing on the abdomen of adult horses does not usually elicit pain unless the affected inflamed or dilated viscus is contacted.

In contrast, parietal pain associated with *peritonitis*, usually is responsive to external palpation. Whereas the animal with visceral pain shows active signs of colic, the animal with parietal pain is usually reluctant to move and has a splinted abdomen. Acute peritonitis occurs within minutes after rupture of the stomach or perforation of an ulcer as a result of immediate irritation of serosal surfaces by the acid contents, whereas with rupture of the colon or rectum it may take 12 hours or more before peritonitis is clinically apparent.

Ruminants exhibit colic less frequently than horses, probably because of a higher threshold for pain and because dietary shifts principally affect the rumen; thus intestinal gas pains occur less frequently. Colic with visceral pain (including urinary tract) is manifested by grinding the teeth (odontoprisis or bruxism), grunting or groaning, treading with the hind feet, kicking at the abdomen, restlessness, repeatedly lying down and getting up, anorexia, and depression. With parietal pain caused by peritonitis, ruminants demonstrate abdominal pain by arching the back, splinting, and exhibiting pain on deep palpation of the area. These signs are seen most commonly with traumatic reticuloperitonitis and abomasal ulcers; rarely are these diseases associated with the colic signs described previously.

7.2.3 Diagnosis and Management of Colic in the Horse

1 Take history. Because colic is a common problem in horses, mild to moderate degrees of abdominal pain are often initially treated symptomatically with analgesics and/or laxatives before major diagnostic efforts are undertaken. Most colic of mild to moderate severity responds favorably to symptomatic treatment. In general, severe pain or pain that is unresponsive to analgesics indicates a more serious condition for which more aggressive medical management or surgical correction may be indicated.

Recurrent mild-to-moderate colic *may*, be an indication of a more serious problem such as bowel entrapment or displacement thromboembolism, internal abscess, enterolith, sand or other foreign body,

tumor, gastric ulcer, hypobiotic cyathostomiasis, *Strongylus vulgaris*, larval migration, heavy burden of ascarids, abdominal adhesions, strictured bowel, or urinary tract disease.

2 Perform physical examination. Intestinal causes of colic can often be differentiated from colic associated with other organ systems (Box 7-8) by physical examination findings and laboratory data. Although extraintestinal origins of acute colic are relatively uncommon in the horse, they include mainly abdominal abscesses, tumors, cholelithiasis or cholestatic disease, and genitourinary tract disease and tend to be recurrent. It is important to note the presence or absence of normal intestinal borborygmi and whether or not feces are being passed in determining whether the problem is extraintestinal. Careful auscultation of the thorax should be performed to evaluate for the presence of diaphragmatic hernias or pleural disease. The testicles should be palpated on all stallions to screen for scrotal hernias or testicular torsions. Rectal examination findings often help to determine anatomic location within gut or other site. Abdominal tumors, abscesses, and other masses may be palpable. Although mild to moderate chronic intermittent colic may be of extraintestinal or intestinal origin, most cases of severe unremitting colic indicate gut involvement, often with anatomic displacement.

104

105

Perirectal abscess

Pheochromocytoma

Purpura hemorrhagica

Biliary atresia

Vaginal or vulvar tear

Cholelithiasis

White muscle disease

Rabies

Rupture of prepubic tendon

Splenitis, splenic abscess, splenomegaly

Cauda equina neuritis with retention of feces or urine

3 Use ultrasound and radiology. Ultrasound may help in locating masses, adhesions, or enlarged liver. It may also be helpful in the diagnosis of gastrointestinal disease, including nephrosplenic entrapment of the large colon and small intestinal distention, and detection of sand from the ventral abdomen may be possible. Ultrasound can be particularly useful in foals and small ruminants because of their size. Radiology can also be useful in detecting enteroliths or sand in adult horses and in some gastrointestinal conditions of foals. Rarely is radiology useful in diagnosing the cause of colic in ruminants, except for urethrographs in sheep and goats to locate a urethral stone.

4 Examine feces. Gross examination of feces should be performed. The presence of sand can often be detected by mixing feces with water in a bucket, then pouring off the water and looking for sediment.

If no feces are passed, a more serious condition is usually indicated, particularly if intestinal sounds are absent.

5 Use laboratory aids. Laboratory aids of immediate benefit in diagnosis and management include PCV and plasma proteins to aid in assessing hydration and vascular integrity and a paracentesis to evaluate abdominal fluid grossly and microscopically. Pain and excitement alone can elevate the PCV, but there is a correlation of elevated PCV (>55%) in colics with nonsurvival. Plasma proteins are not elevated unless blood volume is decreased through shifts in compartmental distribution of body fluids. In colic cases these fluid shifts usually mean that an increased and abnormal amount of extracellular fluid is in the gut lumen, a "third space" where it is of little use in maintaining blood volume. Blood lactate concentration measurement has become routine in evaluation of horses with acute abdominal disease. It is useful in monitoring as an end point to fluid therapy. Some studies have suggested a prognostic role of lactate in horses with colic, although there is marked variability.

Abdominal fluid is normally present in small volume (a few drops to 50 mL); is clear and colorless to yellow; and has a total protein below 2.5 g/dL, specific gravity less than 1.015, little or no fibrinogen (<100 mg/dL), and fewer than 5000 white blood cells (WBCs) per microliter. Elevations in these parameters or increased numbers of neutrophils in peritoneal fluid often indicate inflammation on serosal surfaces. Comparisons of abdominal fluid glucose with serum glucose (greater than 50 mg/dL difference is abnormal) and evaluation of abdominal fluid pH, lactate (as compared with blood lactate), and lactate dehydrogenase (LDH) concentrations can aid in the diagnosis of septic peritonitis.[28] Grossly, fluid changes to cloudy yellow, then to blood-tinged with fibrin clots, and finally to black in color as bowel necrosis and hemolysis of extravasated red blood cells (RBCs) occur. Elevated levels of peritoneal fluid protein are consistently found in anterior enteritis (duodenitis and proximal jejunitis) and provide a useful differential aid, although this finding is also common in cantharidin poisoning. Elevated protein levels are present in peritonitis but accompanied in these cases by elevated numbers of neutrophils. If peritoneal fluid is grossly contaminated with feed material, rupture of a viscus should be considered. Another peritoneal tap in a different location should be undertaken if the possibility of bowel penetration during paracentesis cannot be ruled out. It is not necessary to have abnormal peritoneal fluid before consideration of surgical correction of colic is contemplated. Recently, abdominal fluid lactate has been shown to be predictive of intestinal ischemia secondary to strangulating obstruction and may aid in early detection of intestinal strangulation, rupture, and septic peritonitis.[29]

Many chemical analyses (e.g., lactate) of blood or peritoneal fluid have been recommended as an aid in prognosis and gauging severity of tissue damage. Plasma fibrinogen, as well as peripheral leukocyte counts, can aid in the differentiation of enterocolitis or anterior enteritis from strangulating lesions. Serum electrolyte concentrations and acid-base status are important from a therapeutic standpoint. Serum biochemistries, including liver enzymes, creatinine, and BUN, are important in evaluating for liver and renal compromise. Hyperglobulinemia may be indicative of chronic disease.

6 Evaluate response to treatment. The approach to diagnosis of colic signs is often tied in with management because if the animal's pain cannot be alleviated, surgical intervention and specific diagnosis of displacements, internal hernias, masses, and adhesions are the next steps. The initial diagnosis especially considers the history of deworming and feeding. The findings of the physical examination, including rectal examination and evaluating degree of pain, determine whether additional laboratory workup is indicated. In many cases with mild to moderate pain and no evidence of shock, standard treatment is parenteral administration of an analgesic agent (see Chapter 3) and oral administration of a mild laxative

such as DSS (approximately 1 mL/kg of 5% DSS) or mineral oil (4 L). When a nasogastric tube is passed, the stomach should be checked for reflux and decompressed as needed. The pH of the gastric reflux may indicate primary gastric dilation if acidic, or small intestinal blockage or ileus if alkaline. Dark brown, foul-smelling, and alkaline reflux is often associated with anterior enteritis (duodenitis and proximal jejunitis). If a significant amount of reflux is present, oral medications should be withheld. If cardiovascular function is impaired (poor mucous membrane color and capillary refill, weak pulse, cold extremities, impending shock), sodium-containing fluids should be given intravenously at a rate of 3 to 10 L/hr to a 450-kg horse.

Large amounts of painful gas auscultable in the right flank can be tapped and drawn off, although the risk for peritonitis should be considered. The cecum is trocarized, using a 14- to 16-gauge 6-inch needle inserted through aseptically prepared skin.

The principles of colic management include (1) control of pain, (2) relief of distention, (3) relief of obstruction, and (4) reversal of shock.

7 Perform exploratory surgery. In making a decision concerning management of colic, it is important to separate impending enteritis and peritonitis from bowel disease requiring surgical intervention. Anterior or proximal enteritis can result in prolonged moderate pain and requires constant or frequently repeated analgesic administration and gastric decompression of the foul-smelling, dark reddish-to-brownish stomach contents. However, pain often subsides and is replaced with depression after gastric decompression in horses with anterior enteritis, whereas horses with strangulating lesions often remain in pain. The presence of fever or decreased total WBC count (with neutropenia) may be an indication of impending or ongoing enteritis, in which case surgery may be contraindicated. *Surgery is indicated in the following situations:*, 105 106

a Pain is severe and intractable or nonresponsive or poorly responsive to analgesics.

b Pulse is weak and rate is over 70 beats/min.

c Perfusion is poor, as evidenced by cold extremities, mucous membranes are off color, and capillary refill is poor.

d No gut sounds are auscultated (a lack of fecal production).

e Bowel is markedly distended.

f Large volumes of yellowish alkaline gastric reflux are present.

g Abdominocentesis indicates damaged bowel (blood tinged, increased protein, increased WBCs).

Surgery may be contraindicated in the following situations:,

a Fever

b Neutropenia or marked neutrophilia

c Severe icterus or marked enzyme abnormalities indicating primary liver disease

d Foul-smelling, brownish-red gastric reflux characteristic of proximal enteritis (duodenitis/jejunitis), especially when removal of reflux results in discontinuation of signs of pain

e Evidence of an extraintestinal cause not amenable to surgical correction

f Colitis or diarrhea

g Abnormal behavior or neurologic signs

7.2.4

Diagnosis and Management of Colic in Ruminants

1 Take history. Colic in neonates is most often associated with increased abomasal or intestinal gas and is discussed in Chapter 20. Perforating ulcers are not uncommon as a cause of colic in calves 1 to 6 months of age.

It should be determined whether the onset of colic was acute or whether the colic is chronically recurrent. Few diseases cause recurrent colic in ruminants. Urolithiasis is probably the most common cause of colic in male or neutered male goats and sheep and occurs under varied dietary and environmental conditions. Urolithiasis in cattle occurs most frequently in bulls or steers eating high-grain diets, but silicate stones can occur in very young animals and animals on pasture diet.

2 Perform a physical examination. Take vital signs; with torsion or severe peritonitis, shock signs such as rapid heart rate (>90 beats/min), cold extremities, and weakness may be seen. Tympany can be detected by simultaneous auscultation and percussion. Such causes of colic as cecal dilation, bloat, free gas in the peritoneal cavity, and severe abomasal dilation can be diagnosed in this way (see Figs. 1-3 to 1-5Fig. 1-3). Rectal examination detects such abnormalities as gas in the cecum, uterine abnormalities, urinary tract disease, and intussusception. Observe animal urinating to rule out obstructive urolithiasis.

Ultrasound examination of the abdomen is also useful (see Chapter 32).

3 Examine feces. Observe grossly; intussusception usually has scant dark red (almost black) feces. Scant feces are seen with cecal dilation or displacement.

4 Check preputial hairs and urethral process for sediment and stones. Grit on the preputial hairs is often associated with urolithiasis. Observe animal urinating and check urine for abnormalities. Rule out pyelonephritis.

Radiology and ultrasound can be useful in sheep and goats when urolithiasis is a consideration. Ultrasound can detect a distended bladder, and stones may sometimes be detected. Radiology (lateral view) may detect a stone in the urethra or stones in the bladder. A contrast urethrogram may also be diagnostic.

5 Perform paracentesis to look for peritonitis caused by perforated abomasal ulcer, serosal devitalization, intussusception, or ruptured bladder. Interpret as above for horses, except that normal peritoneal fluid protein concentration can go as high as 5 g/dL in ruminants.

6 Other laboratory aids such as CBC and clinical chemistries are seldom diagnostic in ruminant colic. If grossly abnormal, they may be grounds for formulating a poor prognosis. Intussusception may be associated with neutrophilia (as well as dark feces and colic) in some cases.

7 Symptomatic treatment of colic includes analgesics and, if heart rate is over 90 beats/min, intravenous fluid therapy with a sodium-containing fluid. Take blood sample for electrolytes and acid-base status before initiating fluid therapy.

8 Surgical exploration is indicated if colic is persistent, abdominal distention occurs, the heart rate is over 100 beats/min, feces are scant (especially those that are dark red and indicative of intussusception), there are pings indicating abomasal or cecal displacement or torsion, or the peritoneal fluid indicates bowel devitalization (blood-tinged fluid with elevated protein and WBCs). If surgical exploration is indicated, an important consideration is whether the animal will remain standing under local anesthesia during surgery. It is often best to perform abdominal surgery on animals with colic in left lateral or dorsal recumbency, aided by sedation and restraint, to avoid sudden collapse when painful surgical manipulations are performed. If the left lateral position is selected, use padding to raise the hip and shoulder so that the abdominal viscera can sit in a depression.

7.3

MELENA

BRADFORD P. SMITH,

Melena (dark, tarry feces) is caused by blood in the lumen of the stomach or proximal intestinal tract, resulting in black (digested) blood appearing in the feces (Boxes 7-9 and 7-10). Usually blood is a result of a bleeding ulcer in the stomach or abomasum but may also result from ingestion, oral or pharyngeal bleeding, or coughing up blood that is then swallowed. In ruminants the presence of dark red feces from an intussusception is the main differential to be considered. Blood must stay in the intestinal tract for hours before the hemoglobin is altered and turns black. Small amounts of hemoglobin can be detected by using one of the tests for occult blood. In general, fairly large volumes of blood (1 to 2 L) are required to produce a positive fecal occult blood test in the horse.* A 24- to 48-hour time period is needed for orally administered blood to reach the rectum in the horse. In ruminants, smaller volumes of blood are needed to produce a positive fecal occult test, and a faster transit time is expected.

Hemophilia A, factor VIII deficiency

Bacillary hemoglobinuria

Sulfur toxicity

Warfarin poisoning or other coagulation disorder

Narthecium asiaticum maxim poisoning (exotic)

In approaching a diagnosis, rule out pulmonary, oral, or pharyngeal bleeding. Bleeding of gastrointestinal origin can be determined to be caused by mucosal disease or full-thickness bowel disease (such as an intussusception or neoplasia) by examining peritoneal fluid for abnormalities. Abnormalities in peritoneal fluid are usually present in the case of serosal involvement. Bleeding abomasal ulcers are probably the leading cause of melena in ruminants. They can be silent except for the dark feces and weakness if severe anemia develops. In older horses, gastric squamous cell carcinoma is a frequent cause of gastric hemorrhage. Significant bleeding is much less common in foals and calves with gastric ulcers, and melena is rare in foals and calves with gastric ulcers.

Consideration should be given to whether or not the melena is the result of clotting abnormalities associated with such diseases as DIC or warfarin poisoning. In cattle with colic and dark red-to-black feces, intussusception should be considered likely.

When severe anemia develops, there is evidence of blood loss because the decrease in PCV and RBCs is accompanied by a decrease in plasma proteins. Nonspecific therapy for melena consists principally of blood transfusions in life-threatening cases. Sudden, massive gastric or abomasal bleeding may result in anemia and collapse before melena has appeared.

In the foal, gastric ulcers may be treated with histamine-2 (H_2) blockers such as ranitidine or cimetidine. These drugs are probably less effective in ruminants. Their benefit in ruminants with abomasal ulcers is not well understood at present. New drugs such as the hydrogen pump blocker omeprazole are useful and potent gastric pH effectors. Therapy with protectants such as sucralfate (which coats the ulcer) is a viable and clinically useful therapy in the horse. In ruminants, orally administered protectants and antacids are so diluted by the time they reach the abomasum that they are probably of limited benefit.

* Carlson G: Personal communication, 1990.

7.4

BLOOD, FIBRIN, AND/OR MUCUS IN FECES (DYSENTERY)

BRADFORD P. SMITH,

Bloody diarrhea is termed *dysentery*., The presence of fresh blood or clots in the feces is termed *hematochezia*, and is the result of bleeding into the distal intestinal tract. Occasionally blood from the female reproductive tract may appear in or on the feces. Fibrin indicates severe inflammatory bowel disease. Fibrin appears as casts, chunks of yellow-gray material, or mucosa-like sheets. Mucus in feces increases with inflammatory bowel diseases such as salmonellosis. It is often seen when fecal volume is small in animals that are anorectic, in which case the feces are often coated with mucus. This mucous coating can become very obvious in the horse and is not a sign of bowel disease in this case.

Frank blood in feces without diarrhea and other evidence of gastrointestinal dysfunction or systemic illness may be a result of a bleeding disorder, a traumatic foreign body, rectal examination trauma, sadistic rectal trauma, or rectal trauma in a mare from a stallion penetrating the rectum (Boxes 7-11 and 7-12). Many of the diseases listed as causes of melena may also result in gastrointestinal hemorrhage and are therefore listed in both places. If the bleeding is in the distal gastrointestinal tract, fresh blood may be seen in the feces. With diseases midway down the tract, such as intussusception, fecal material is dark red and may appear black until a sample is examined closely and spread on a white surface.

7.5 ABDOMINAL DISTENTION AND CONSTIPATION

BRADFORD P. SMITH,

Abdominal distention may be caused by feed, fluid, gas, feces, or a neoplasm (Boxes 7-13 and 7-14). Pregnancy or extreme obesity may also result in an enlarged abdomen. The physical examination should determine which of these is the most likely cause. Often in ruminants the distention can be seen as primarily left sided, right sided, or bilateral. For example, bloat in ruminants results in a characteristic high left-sided gas distention. It may be primary or associated with vagal indigestion, tetanus, or hypocalcemia. With vagal indigestion the rumen becomes enlarged and fluid-filled, often giving a pear shape to the abdomen as it is viewed from the rear, or a pear shape on the right and an apple shape on the left (“papple” shape) if some degree of bloat is also present. Hypocalcemia and hypokalemia contribute to ileus and may result in constipation and abdominal enlargement. In sheep, abomasal impaction and enlargement associated with abomasal emptying defects can result in an enlarged abdomen with

decreased food intake. When a mass (most commonly an abscess, a tumor, or a fat necrosis [cattle only]) obstructs fecal passage, abdominal enlargement can become severe. With obstructive disease, some degree of colic is almost always present. Ruptured bladder results in a large fluid-filled abdomen, but constipation is not an obvious sign.

The most common causes of decreased fecal output in ruminants and horses are decreased feed intake and dehydration. In such cases the animal will appear gaunt or have a relatively empty abdomen or rumen. Horse feces in cases of prolonged transit are often covered with a layer of tenacious, thick, yellow mucus. When a functional obstruction (ileus, vagal indigestion) or physical obstruction (impaction, foreign body, displaced intestine, fat necrosis) occurs as a cause of constipation, the abdomen is more likely to appear normally full or to become distended. Rectal examination is of great help in determining whether a mass or an obstruction exists because loops of distended small bowel can sometimes be palpated in the latter case.

Radiographs and ultrasound may be valuable to help determine the cause of abdominal distention in foals, calves, and small ruminants. Increased gastrointestinal gas may result in abdominal distention. Abomasal bloat and necrotizing enterocolitis in young animals may best be confirmed with lateral abdominal radiographs.

Dehydration may also result in dry feces but not in abdominal enlargement. When constipation is present and feces are drier than normal, rehydration and correction of hypocalcemia, hypokalemia, and any existing acid-base abnormalities are important parts of correction of the constipation. Other nonspecific therapies for functional constipation include laxatives, cathartics, and cholinergic drugs. When treating constipation, which is usually a secondary problem, it is important to simultaneously attempt to diagnose the primary disease.

In ruminants, when abdominal distention involves the rumen or is caused by pregnancy or obesity, colic is absent. When abdominal distention is the result of obstruction from the pylorus distal, colic is usually present. Abdominal distention and constipation are frequently accompanied by colic in the horse, regardless of anatomic site involved (review the approach to colic).

7.6 REGURGITATION AND VOMITING

BRADFORD P. SMITH,

Regurgitation is the reflux of esophageal, gastric, or rumen contents into the mouth or nose. This may be caused by malfunction of the esophagus or in ruminants as part of the normal physiology for rechewing ingested plant fiber (Boxes 7-15 and 7-16). Vomiting is a coordinated, centrally (medulla) mediated event, usually preceded by nausea (inappetence), increased salivation, or retching. In vomiting the abdominal musculature contracts, the diaphragm is pushed caudally, and the cardia relaxes. The medullary vomiting center can be stimulated by visceral afferent stimuli or through the chemoreceptor trigger zone. Most toxins and drugs that cause vomiting act by directly affecting the chemoreceptor trigger zone. Other than with toxins, most cases of feed returning to the mouth in large animals are examples of regurgitation rather than true vomiting. Vomiting is unusual in both ruminants and horses.

Although regurgitation is a normal phenomenon in ruminants, it is unusual to find excessive regurgitation as a sign of disease. Physical blockage of rumenoreticular outflow by a foreign body, warts, granulomas, or diaphragmatic hernia can cause rumen distention and excessive regurgitation after eating. An esophageal foreign body can cause irritation and result in regurgitation. Animals with facial paralysis may drool feed and saliva on the affected side; this should be differentiated from animals with excessive or abnormal regurgitation. Vomiting or forced regurgitation in ruminants is rare and is seen principally with the toxins listed.

7.6.1 Box 7-15 Causes of Regurgitation and Vomiting in Horses

Horses have such a marked tone at the cardiac sphincter that vomiting occurs only when extreme intragastric pressures develop, usually in small intestinal obstructive diseases or proximal enteritis. Vomiting in the horse thus often occurs with gastric rupture or terminally with shock. Stomach contents are usually pH 5 or below. Because it is a terminal event, vomiting in the horse is often grounds for rendering a poor prognosis. Abdominocentesis should be performed on a horse after vomiting to rule out gastric rupture. To avoid this sequence of events, decompression using a nasogastric tube should be performed in any horse with evidence of gastric distention (see approach to colic). Regurgitation and vomiting in horses most commonly occur from the nose rather than into the mouth, because of the anatomy of the soft palate. With choke (esophageal obstruction), esophageal regurgitation from the nares consists of mixed feed and saliva.

In foals a few weeks to several months of age, milk returning from the nares is often associated with gastric ulceration, along with signs of colic, lying in dorsal recumbency, hypersalivation, and champing movements of the mouth. In advanced cases with duodenal ulcers, pyloric outflow can be obstructed by scarring, resulting in more pronounced signs. Foals 1 to 6 months of age are most susceptible to gastric ulceration.

Occasionally, neonatal foals without cleft palate have some mild degree of dysphagia with milk regurgitation from the nose for the first 24 to 48 hours of life, which spontaneously corrects. The cause of this is unknown, but it would appear to be a failure of normal swallowing events to be sufficiently strong or coordinated in the newborn. The major ruleout in these cases is cleft palate.

7.6.3

Approach to Diagnosis of Regurgitation and Vomiting

Evaluation of regurgitation or vomiting should include a history to determine possible exposure to toxins or poison plants, which is most likely when multiple animals are affected. Age of the animal limits some considerations; young animals are more prone to meningitis and central nervous system (CNS) trauma, and congenital problems such as esophageal diverticula and persistent right aortic arch are found only in neonates and may not manifest as choke or regurgitation until solid food intake is increased.

The physical examination can determine whether the problem is vomiting or regurgitation. In ruminants, regurgitation often occurs as a result of distention and overfilling of the rumen, resulting in an obviously distended abdomen. Painful pharyngeal lesions can also cause pharyngeal paresis, which results in gagging and regurgitating. In horses the most common causes of feed coming from the nares are spontaneous choke and pharyngeal paresis associated with guttural pouch lesions (see section on dysphagia).

Physical examination should also include passing a stomach tube to determine whether any impediment to passage of ingesta is present (Box 7-17). Endoscopy is useful to visualize esophageal defects. Many endoscopes currently in use are not long enough to reach the stomach of the adult horse. Endoscopy of the rumen is rarely diagnostic, because it is almost impossible to empty it adequately to allow for visualization of a lesion. Ultrasound of the cervical esophagus may also be useful.

110

111

7.6.3.1

Box 7-17 Useful Techniques in Diagnosing Cause of Regurgitation

- Passing of stomach tube
- Endoscopy of pharynx, guttural pouches, esophagus, and stomach
- Ultrasound examination of the cervical esophagus may be helpful
- Radiographs; plain films of pharynx, guttural pouches, esophagus, and stomach
- Radiographs, barium swallows, checking gastric emptying time in horse

In horses and small ruminants radiography, particularly barium contrast studies, can be useful in detecting esophageal abnormalities. In foals, prolonged gastric emptying time may be diagnosed from contrast studies. Normal emptying and movement of contrast media into small bowel occur in less than 2 hours; contrast media reach the large bowel by 3 hours. Radiography may also be useful in detecting diaphragmatic hernia.

The most significant complications of regurgitation and vomiting include aspiration pneumonia, dehydration, and electrolyte imbalances. The marked hypochloremic alkalosis common to most monogastrics is rare in horses and occurs in ruminants mainly with internal vomiting (one type of vagal indigestion) associated with reflux of abomasal contents back into the rumen.

Vomiting, like diarrhea, is often an attempt by the body to rid itself of a noxious or toxic substance. Antiemetics are therefore rarely indicated in vomiting of central origin and rarely effective in regurgitation in large animals.

7.7

DYSPHAGIA (INCLUDING FEED FROM NARES AND EXCESSIVE SALIVATION)

BRADFORD P. SMITH,

Dysphagia, is used here to refer to abnormalities of prehension, mastication, or swallowing. It is associated with diseases of the mouth, lips, pharynx, esophagus, mandible, or masseter muscles or, in the case of neurologic problems, with central or peripheral lesions resulting in malfunction in these areas. Diseases resulting in erosions, ulcers, swellings, crusts, or growths in or on the lips, mouth, or pharynx are discussed under a separate heading. Painful causes of dysphagia such as dental problems require differentiation from oral lesions such as ulcers.

7.7.1

Box 7-18 Causes of Dysphagia in Horses

7.7.1.1

PAIN

Tooth root abscess or periodontal disease

Worn, missing, capped, overgrown, or broken teeth

Foreign body in mouth, pharynx, nose

West Nile fever

Borna disease, Near East encephalitis (exotic)

Grass sickness (exotic)

The causes of dysphagia can be divided into three categories: (1) pain induced, (2) neurologic, and (3) obstructive (Boxes 7-18 and 7-19). A fourth category is mechanical interference with prehension and swallowing, but this usually manifests in a manner resembling the manifestation of painful lesions. Particularly in horses, worn, missing, capped, abscessed, overgrown, or broken teeth often result in mechanical interference with chewing, resulting in half-chewed feed being dropped from the mouth (quidding). Observation of the animal as it attempts to eat and a good physical examination, including oral inspection and passage of a stomach tube to rule out choke, are essential in determining the cause of dysphagia. Use of a fiberoptic endoscope to visualize the pharynx, guttural pouches, and esophagus may be helpful. Plain film radiographs and barium swallows may also be indicated to see functional abnormalities in the pharynx and esophagus during swallowing and to rule out fractures of the hyoid or mandible. Ultrasound should also be employed.

Pain is probably the most frequent cause of dysphagia in ruminants and horses. Oral lesions, oral foreign bodies, and poor teeth result in decreased feed intake, in increased salivation, and often in dropping feed from the mouth while attempting to chew. Dental problems are relatively common in sheep and goats. In cattle, pharyngeal injuries from balling guns and paste wormers can result in severe pharyngeal cellulitis, which is manifested by an extended head, ptyalism, foul breath, and a painful, externally palpable, pharyngeal swelling. Mandibular fractures must be ruled out by careful examination, because even nondisplaced unilateral mandibular fractures can result in weak jaw tone, reluctance to eat, and drooling.

Ephemeral fever (exotic) (B)

B, Bovine.

When dysphagia is associated with loss of large amounts of saliva, metabolic acid-base and electrolyte disorders may develop. Cattle and sheep have saliva high in sodium (136 to 201 mEq/L) and bicarbonate (108 mEq/L), with potassium and chloride values in the 14 to 15 mEq/L range.[30,31] As a result, losses of large amounts of saliva can result in hypovolemia and severe metabolic acidosis. In contrast, horses have relatively high levels of salivary chloride (48 to 82 mEq/L) with relatively low salivary bicarbonate (44 to 52 mEq/L). Equine salivary potassium is 14 to 18 mEq/L, and sodium 54 to 90 mEq/L.[32,33] As a result, horses with esophageal fistulas that lost saliva had a transient metabolic alkalosis.[32]

In the horse a common cause of acute dysphagia is choke (esophageal obstruction), followed in frequency by pharyngeal paresis (neurologic) resulting from lesions in the guttural pouch that affect the pharyngeal nerves. Feed coming from the nose is the most obvious sign of both of these conditions. In choked horses, as a result of the

length and position of the soft palate, feed comes mainly from the nares rather than coming back into the mouth. Choke and other obstructive diseases can be easily identified by using a nasogastric tube, whereas pharyngeal paresis may be associated with a number of neurologic or neuromuscular conditions, such as botulism or guttural pouch mycosis, which require careful differentiation. The most frequent serious problem associated with choke or pharyngeal paresis is inhalation (aspiration, foreign body) pneumonia. Mineral oil or other material that is particularly damaging if it gains entry into the lung should never be used in choke for this reason. In any animal with dysphagia, care must be taken to prevent aspiration pneumonia and to evaluate the thorax periodically.

Animals with facial paralysis often drool from the affected side and may pack feed into the cheek on the affected side. Listeriosis in ruminants is frequently associated with facial paralysis. In horses facial paralysis is usually caused by halter trauma or a blow to the head.

7.8

ORAL VESICLES, EROSIONS, ULCERS, OR GROWTHS

BRADFORD P. SMITH,

Oral lesions are found with many conditions (Boxes 7-20 and 7-21). In general, they result in some degree of dysphagia or reluctance to eat because of pain. The lesions include vesicles, erosions, ulcers, crusts, or growths in or on the lips, tongue, gums, palate, or pharynx. Oral lesions are often associated with champing and increased amounts of saliva being observed on the lips or running from the mouth. When the volume of saliva is increased, the condition is called *ptyalism*, and the animal may be observed swallowing repeatedly. *Pseudoptyalism*, refers to a normal volume of saliva that because it is not swallowed is visible to the observer and may be confused with dysphagia (see previous section).

7.8.1

Box 7-20 Conditions Accompanied by Oral Vesicles, Erosions, Ulcers, or Growths in Horses

7.8.1.1

COMMON CAUSES

Vesicular stomatitis

Phenylbutazone toxicity

Yellow bristle grass (*Setaria lutescens*, or *Setaria glauca*) ulcers

Other plant awn stomatitis

Oral foreign body

7.8.1.2

LESS COMMON CAUSES

Irritant or caustic chemical stomatitis

Periodontal gingivitis

Blister beetle (cantharidin) toxicity

Uremia

7.8.2 Box 7-21 Conditions Accompanied by Oral Vesicles, Erosions, Ulcers, or Growths in Ruminants

7.8.2.1 COMMON CAUSES

Bluetongue (O)

Contagious ecthyma (Orf virus) (O, C)

Bovine viral diarrhea/mucosal disease (B)

Bovine papular stomatitis (B)

Traumatic or irritant stomatitis

Bristle grass (*Setaria lutescens*, or *Setaria glauca*) ulcers

Other plant awn stomatitis

Oral foreign body

Actinobacillosis (woody tongue)

Vesicular stomatitis

7.8.2.2 LESS COMMON CAUSES

Actinomycosis (lumpy jaw)

Cheek abscess

Periodontal gingivitis

Oak or acorn toxicity

Malignant catarrhal fever (B)

Irritant or caustic chemicals

7.8.2.3 UNCOMMON CAUSES

Caprine herpes virus (C)

Necrotic stomatitis

Epidermolysis bullosa

Familial acantholysis (B)

Oral neoplasia

Epitheliogenesis imperfecta

Hereditary zinc deficiency (baldy calf) (B)

Electrical injury

Bovine herpes 2 mammillitis (B)

Elaeophorosis (O)

Chlorinated naphthalene toxicity (B)

Thallium toxicity (O)

Giant hogweed *(Heracleum mantegazzianum)*, toxicity

Lead toxicity

Mycotoxicoses
Ibaraki disease (exotic) (B)
Lumpy skin disease (exotic) (B)
Sweating sickness (exotic) (B)
Sheep and goat pox (exotic) (O, C)
Peste des petits ruminants (exotic) (O, C)

B, Bovine; *C*, caprine; *O*, ovine.

The approach to determining the cause of oral lesions is based on first determining whether the cause is likely to be an infectious disease (Table 7-1). Essentially all these infectious diseases are associated with a fever, although it is short-lived and moderate in the case of bovine papular stomatitis (BPS) and actinobacillosis. Papular stomatitis rarely causes illness and is usually an incidental finding in calves with a different clinical problem. Most of the infectious diseases are associated with additional lesions or symptoms. They can be conveniently grouped into those causing diarrhea and those not usually associated with diarrhea. Of those not associated with diarrhea in North America, BPS, actinobacillosis, and vesicular stomatitis (VS) are most common in cattle; VS in horses; bluetongue in sheep; and contagious ecthyma (CE) in sheep and goats. CE can be readily differentiated from bluetongue because it involves primarily lips and gums and is proliferative, whereas bluetongue involves the tongue and dental pad most severely, is erosive, and is associated with other signs of generalized vasculitis. Laboratory diagnosis in acute cases of VS is done by working with state and federal veterinarians. Because VS is highly contagious and similar in clinical appearance to foot-and-mouth disease, quarantine and proper diagnosis are essential. Bluetongue is diagnosed by serology (AGID), PCR, and virus isolation. CE can be diagnosed serologically, by fluorescent antibody on the impression smear or biopsy of a lesion, and by isolation. Asymptomatic seroconversion to bluetongue is common where *Culicoides*, vectors are active. Congenital defects can result from bluetongue infection of the fetus in sheep, goats, and cattle.

The two most common North American infectious diseases associated with oral lesions and diarrhea in cattle are bovine viral diarrhea/mucosal disease (BVD/MD) and MCF. MCF can usually be differentiated because it most commonly occurs sporadically in single animals and has signs of generalized vasculitis such as bilateral corneal opacity, mucopurulent nasal discharge, enlarged lymph nodes, and very high fever. Dysentery is common in MCF, and some animals exhibit CNS signs or have thickened and cracking skin. Laboratory diagnosis in acute cases of BVD (see Chapter 32) involves fluorescent antibody testing of slides made from ear notch biopsies, lesion swabs, buffy coat, or tissue. Virus isolation from swabs, serum, or blood or a rise in serum titer from acute to convalescent samples is also diagnostic. Asymptomatic seroconversion is also common, and infection of the fetus may result in congenital anomalies, including cerebellar hypoplasia in cattle.

In animals without fever and other signs of systemic involvement, irritants and caustic chemicals should be considered as possible causes of oral lesions. Horses and young calves are susceptible to severe ulceration when consuming hay contaminated with yellow bristle grass, which is armed with barbed bristles.[34] Horses sometimes

develop gingivitis or oral ulcers associated with dry plant awns called *foxtails*, which become embedded into the gums around teeth. Foals and ponies are most susceptible to phenylbutazone toxicity, which can produce oral ulceration. In cattle the surfaces of masses produced by actinobacillosis and actinomycosis sometimes ulcerate. Many cattle without significant disease have one or more small ulcers of traumatic origin from plant awns on the hard palate and in the cleft (sulcus lingualis) where the base and shaft of the tongue meet.

Table 7-1 Infectious Diseases Associated with Oral Lesions in Cattle, Sheep, Goats, and Horses

Disease	Natural Species	Oral Lesions	Other Lesions
Vesicular stomatitis (VS)	Cattle Horse Sheep (rare)	Vesicles for short time, then large ulcers; tongue usually severely involved	Teats and feet may be involved
Bluetongue	Sheep Goat (rare) Cattle (rare)	Large oral ulcers; dental pad and tongue most affected; generalized vasculitis	Coronitis, muscle degeneration, lameness, pulmonary edema, edema of face and ears
Contagious ecthyma (CE; Orf)*	Sheep Goat	Proliferative scabby lesion on lips to fleshy growth on gums	Occasionally on teats of nursing dams
Bovine papular stomatitis*	Cattle	Round, dark red, raised papules on muzzle and on hard palate	Occasionally in esophagus
Foot-and-mouth (exotic)	Cattle Sheep Goat	Vesicles for short time, then large ulcers	Teats and coronary bands often involved
Bovine viral diarrhea/ mucosal disease (BVD/MD)	Cattle	Ulcers in mouth, particularly on hard palate; erosive stomatitis	May have skin lesions; a few have corneal edema or enlarged lymph nodes; pneumonia and lesions in esophagus and gastrointestinal tract common; severe diarrhea
Malignant catarrhal fever (MCF)	Cattle	Erosive stomatitis with ulcers; generalized vasculitis	Purulent nasal discharge, corneal edema, enlarged lymph nodes, ± cracking skin, ± central nervous system signs; severe diarrhea; high fever
Rinderpest (exotic)	Cattle Sheep Goat	Erosive stomatitis	Blepharospasm, severe intestinal involvement, and diarrhea
Alimentary form of infectious bovine rhinotracheitis (IBR) in calves	Cattle	Gray pinpoint pustules on soft palate and occasionally in nares; minimal oral lesions	Rhinotracheitis, conjunctivitis, pneumonia

* Infectious to humans.

7.9 DENTAL ABNORMALITIES

BRADFORD P. SMITH,

Chronic fluorosis is a cause of a variety of dental abnormalities in young animals with developing teeth (Boxes 7-22 and 7-23). Although cattle are most frequently involved, all large animals are susceptible. The teeth may appear mottled, striated, chalky, or hypoplastic or may have defective calcification. In severe cases teeth may be yellow, brown, or black and have multiple caries. Animals of any age may also develop bone lesions associated with chronic fluorosis.

7.9.1 Box 7-22 Causes of Dental Cavities, Abnormalities of Tooth Color, and Loose Teeth in Horses

Periodontal disease

Chronic fluoride toxicity

Dental decay

Fractured teeth

Osteomalacia, osteodystrophy

Halicephalobus (Micronema) deletrix, granulomas of mandible or maxilla

Skeletal neoplasia of mandible or maxilla

Hyperparathyroidism

Tooth root abscess with osteomyelitis, secondary to open infundibulum

Ameloblastoma (odontoma)

Dental stain (black walnut hull ingestion or other compound)

Porphyria is a rare congenital condition of cattle transmitted by a simple autosomal-recessive gene. The teeth often appear pink because of the presence of porphyrins and fluoresce pink, purple, or red when exposed to ultraviolet light. Affected calves often develop photosensitization and anemia. This condition must be differentiated from superficial staining caused by ingestion of black walnut hulls or other compounds with staining properties. 114 115

7.9.2

Box 7-23 Causes of Dental Cavities, Abnormalities of Tooth Color, and Loose Teeth in Ruminants

Chronic fluoride toxicity

Bovine erythropoietic porphyria

Fractured teeth

Osteogenesis imperfecta in Friesians

Osteomalacia, osteodystrophy

Actinomycosis

Skeletal neoplasia of mandible or maxilla

Lymphosarcoma (goat and sheep)

Periodontal disease

Broken mouth (old worn teeth)

Tooth root abscess with osteomyelitis

Ingestion of black walnut hulls or other dental stain

Excessive or uneven wear or loss of teeth is often seen in horses and ruminants as they age. Tooth wear, particularly of incisors, is more rapid in animals on sandy range. Periodontal disease can cause premature loss of teeth (broken mouth) and tends to be most common in sheep in some geographic areas; the cause of this is unknown.[35]

The most common dental disease in horses has been described as periodontal disease.[36] In horses fractured teeth or teeth with a small tract into the root through an open infundibulum often result in tooth root abscesses. This dental decay is a result of hypoplasia of the cementum of the enamel lakes and occurs most frequently in the second and third lower cheek teeth and third and fourth upper cheek teeth.[37] These can cause sinusitis and foul-smelling unilateral nasal discharge if upper cheek teeth are involved or draining tracts to the exterior skin surface if lower cheek teeth are involved.

Most of the other causes of dental abnormalities listed here are bone abnormalities that cause secondary loss of teeth. See Chapter 32 for more details.

7.10 ICTERUS (JAUNDICE)

BRADFORD P. SMITH,

Icterus, and *jaundice*, are synonymous terms referring to the expression of a yellow coloration in the sclera and mucous membranes resulting from increased amounts of bilirubin in tissues and increased serum bilirubin levels (Boxes 7-24 and 7-25). Bilirubin especially stains elastic tissues and is thus most visible in the sclera and vulva. Icterus usually indicates *decreased excretion*, of bilirubin with liver or biliary tract diseases or *increased production*, of bilirubin with hemolytic anemia.

7.10.1 Box 7-24 Causes of Icterus in Horses

7.10.1.1 LIVER

7.10.1.1.1 Common Causes

Pyrrolizidine alkaloid toxicity

Serum-associated hepatitis

Acute hepatitis

Chronic active hepatitis

Cholangitis or cholangiohepatitis

Bile stones, other biliary obstruction

Fasting hyperbilirubinemia

7.10.1.1.2 Less Common Causes

Aflatoxicosis with liver failure

Tyzzer's disease (foals)

Hepatic lipidosis

Hepatic abscess

7.10.1.1.3 Uncommon Causes

Black disease (infectious necrotic hepatitis)

Hemangioma, hemangiosarcoma, angiosarcoma

Cardiac neoplasm

Viral arteritis

Gastric or duodenal ulcers

Severe ascarid infection

Lymphosarcoma

7.10.1.2 HEMOLYTIC ANEMIA

7.10.1.2.1 Common Causes

Immune-mediated hemolytic anemia

Ehrlichiosis *(Ehrlichia equi)*,

Neonatal isoerythrolysis

7.10.1.2.2 Less Common Causes

Piroplasmosis (babesiosis)

Snake bite

Blood transfusion

Erythrocytosis

7.10.1.2.3 Uncommon Causes

Equine viral arteritis

Leptospirosis

Bee or wasp sting

Sulfur toxicity

Trichloroethylene-extracted feed

Iron toxicity

Phosphorus toxicity

Herbicide toxicity

Phenothiazine toxicity

White snakeroot poisoning (tremetol)

Onions

Red maple *(Acer rubrum)*,

Pentachlorophenol toxicity

Oak toxicity

Mycotoxicosis

Surra, *Trypanosoma evansi*, (exotic)

Mal de caderas, *Trypanosoma equinum*, (exotic)

Murrina de caderas, *Trypanosoma hippicum*, (exotic)

The accumulation of conjugated bilirubin results in more pronounced jaundice than does a similar amount of unconjugated bilirubin, with the result that the most pronounced jaundice is usually seen with hepatic or biliary obstructive disease. Laboratory examination of serum for relative amounts of unconjugated (indirect reacting) and conjugated (direct reacting) bilirubin is essential in determining the cause of the icterus. Generally, mainly unconjugated bilirubin levels are elevated with hemolytic anemia. Anorectic horses may have a plasma unconjugated bilirubin of 5 or 6 mg/dL without any evidence of hemolytic anemia or liver disease. Anorectic ruminants also experience a rise in plasma unconjugated bilirubin, often to a level between 0.5 and 2 mg/dL.

In determining the cause of icterus, laboratory tests, including PCV, RBC count, and the liver enzymes SDH and GGT, should be determined. In horses, alkaline phosphatase (AP) may also be useful, although it is not liver specific.

When active hepatocellular damage is occurring, SDH, which is liver specific, and aspartate aminotransferase (AST [SGOT]), which is not liver specific, are found in serum in elevated levels. GGT and AP are more indicative of biliary tract disease or proliferation and tend to rise more slowly but also to remain elevated for a longer period than SDH, which has a short half-life. Elevated levels of GGT or AP are often associated with chronic liver disease, cholangitis, cholelithiasis, or liver flukes. *It is possible to have liver disease without icterus*., Production and elimination of bilirubin are often equal in chronic liver disease, but acute liver disease or liver failure is usually associated with icterus. Although liver function tests such as BSP half-time can be run to determine the extent of liver damage, in most cases a liver biopsy must be taken for histopathologic examination to make a specific etiologic diagnosis of the cause of liver disease.

115

116

7.10.2 Box 7-25 Causes of Icterus in Ruminants

7.10.2.1 LIVER

7.10.2.1.1 Common Causes

- Pyrrolizidine alkaloid toxicity
- Aflatoxicosis
- Fat cow syndrome (fatty liver)

7.10.2.1.2 Less Common Causes

- Acute hepatitis
- Liver flukes
- Infectious necrotic hepatitis (black disease)
- Liver abscess

Cholangiohepatitis

7.10.2.1.3 Uncommon Causes

Sarcocystosis

Hepatic neoplasia

Ruptured gallbladder

Cholelithiasis

Biliary obstruction

Nolina, (beargrass) toxicity

Lantana, toxicity

Agave, toxicity

Wesselsbron disease (exotic) (B, O)

7.10.2.2 HEMOLYTIC ANEMIA

7.10.2.2.1 Common Causes

Leptospirosis

Anaplasmosis

Bacillary hemoglobinuria *(Clostridium hemolyticum)*,

Piroplasmosis, babesiosis (exotic)

7.10.2.2.2 Less Common Causes

Snake bite

Immune-mediated hemolytic anemia

Transfusion reaction

Postparturient hemolytic anemia

Copper toxicity (especially sheep)

Neonatal isoerythrolysis

Yellow lamb disease (*Clostridium perfringens*, type A) (O)

7.10.2.2.3 Uncommon Causes

Anaplasma ovis

Eperythrozoonosis

Bee or wasp sting

Brassica species toxicity

Trichloroethylene-extracted feed toxicity

Iron toxicity

Onion poisoning

Zinc poisoning

Phosphorus poisoning

Mercury poisoning

Fireweed *(Kochia scoparia)*, poisoning

Mycotic lupinosis

	Mycosporum poisoning
	Theileriosis (East Coast fever) (exotic)

B, Bovine; *O*, ovine.

Liver abscesses rarely result in icterus because they rarely damage a sufficient percentage of liver to impair bilirubin clearance. They do cause multifocal hepatic damage and therefore are often associated with increased levels of SDH and AST when in the acute stages of formation.

Hemolytic anemia is characterized by destruction of RBCs either intravascularly or in the reticuloendothelial organs. This increased destruction results in production of bilirubin more rapidly than it can be removed by the liver, resulting in icterus. The specific cause of hemolytic anemia may sometimes be evident, as when autoagglutination is seen (autoimmune hemolytic anemia), *Anaplasma*, bodies are visible in stained RBCs of cattle, or *E. equi*, blue cytoplasmic inclusion bodies are seen in stained neutrophils.

In mature sheep, the most common cause of severe icterus is copper toxicity. In lambs, yellow lamb disease caused by *C. perfringens*, type A is a leading cause.

8 Chapter 8 Localization and Differentiation of Neurologic Diseases

Mary O. Smith

Consulting Editors

Lisle W. George, *

8.1 TERMINOLOGY AND DESCRIPTION OF CLINICAL SIGNS OF NEUROLOGIC DISEASE (TABLE 8-1)

Telencephalon (cerebrum, basal ganglia) and diencephalon (thalamus)

Changes in behavior

Changes in the level of consciousness

Dullness, obtundation

Stupor

Coma

Excitement, mania

Seizures (convulsions)

Narcolepsy

Vision disturbance

Blindness in both visual fields (amaurosis)

Blindness in the contralateral visual field (hemianopsia)

Menace reflex deficit

Change in pupil size: small to pinpoint pupils

Circling (toward the side of the lesion)

Head turn (toward the side of the lesion)

Gait usually normal

Abnormal postural reactions (contralateral)

Decreased or absent conscious proprioception

Noticeable ataxia, paresis (weakness), or paralysis are uncommon

Abnormal spinal reflexes

Normal to increased (hyperreflexic) myotactic reflexes

Altered muscle tone

Normal to increased muscle tone (spasticity)

Urinary incontinence (upper motor neuron)

Tremors

Mesencephalon (midbrain)

Changes in the level of consciousness

Dullness (depression)

Stupor

Coma

Narcolepsy

Abnormal posture

Opisthotonos

Decerebrate posture

Abnormal visual or ocular function

Blindness in both visual fields (amaurosis)

Blindness in the contralateral visual field (hemianopsia)

Change in pupil size

Small pupils in early, mild lesions

Dilated, nonresponsive pupils in severe lesions

Menace reflex deficit (ipsilateral)

Anisocoria (asymmetric lesions)

Circling (toward side of lesion—ipsiversive)

Head turn (toward side of lesion—ipsiversive)

Abnormalities of gait (usually contralateral to lesion)

Decreased or absent conscious proprioception

Ataxia

Paresis (weakness)

Paralysis

Abnormal spinal reflexes

Normal to increased (hyperreflexic) myotactic reflexes

Altered muscle tone

Spasticity

Urinary incontinence (upper motor neuron)

Metencephalon (pons, cerebellum)

Abnormal posture

Head tilt

Decerebellate posture

Circling (usually away from side of lesion—paradoxic signs)

Head turn (usually away from side of lesion—paradoxic signs)

Nystagmus (variable—may be constant, positional, direction changing, or disconjugate and may occur in any direction)

Abnormalities of gait

Ataxia

Dysmetria—typically, hypermetria

Abnormal spinal reflexes (occasional)

Normal to increased myotactic reflexes (hyperreflexia)

Altered muscle tone

Normal to increased muscle tone on the opposite side of the body (contralateral spasticity)

Normal to decreased muscle tone on the same side of the body (ipsilateral hypotonus)

Urinary incontinence (upper motor neuron) (rare)

Medulla oblongata

Changes in the level of consciousness

Dullness, obtundation

Abnormal posture

Head tilt (toward side of lesion—ipsiversive)

Circling (toward side of lesion—ipsiversive)

Head turn occasionally (toward side of lesion)

Strabismus—variable

Nystagmus—spontaneous, abnormal (variable—may be constant, positional, direction changing, or disconjugate and may occur in any direction)

Dysphagia

Facial anesthesia, analgesia

Facial paresis or paralysis

Menace reflex deficit

Jaw weakness

Roaring, snoring, dysphonia

Tongue weakness, deviation, or paralysis

Abnormalities of gait—ipsilateral

Decreased or absent conscious proprioception

Ataxia

Paresis (weakness)

Paralysis

Abnormal spinal reflexes

Normal to increased (hyperreflexic) myotactic reflexes

Altered muscle tone

Normal to increased muscle tone

Urinary incontinence (upper motor neuron)

Spinal cord C1-C5

Abnormalities of gait in thoracic and pelvic limbs—ipsilateral

Decreased or absent conscious proprioception

Ataxia

Paresis (weakness)

Paralysis

Abnormal spinal reflexes—ipsilateral

Hyperreflexia in both thoracic and pelvic limbs

Decreased to absent caudal cervical and auricular reflexes

Decreased to absent slap test (horses)

Altered muscle tone

Normal to increased muscle tone

Urinary incontinence (upper motor neuron)

Spinal cord C6-T2

Abnormalities of gait in thoracic and pelvic limbs—ipsilateral

Decreased or absent conscious proprioception

Ataxia

Paresis (weakness)

Paralysis

Abnormal spinal reflexes—ipsilateral

Hyporeflexia in thoracic limbs

Hyperreflexia in pelvic limbs

Decreased to absent caudal cervical and auricular reflexes

Decreased to absent slap test (thoracolaryngeal reflex, horses)

Absent panniculus reflex

Horner's syndrome (ipsilateral)

Altered muscle tone

Decreased muscle tone in thoracic limbs

Normal to increased muscle tone in pelvic limbs

Urinary incontinence (upper motor neuron)

Spinal cord T3-L2

Abnormalities of gait in pelvic limbs only—ipsilateral

Decreased or absent conscious proprioception

Ataxia

Paresis (weakness)

Paralysis

Abnormal spinal reflexes—ipsilateral

Hyperreflexia in pelvic limbs only

Decreased panniculus reflex caudal to lesion

Altered muscle tone—ipsilateral

Normal to increased muscle tone in pelvic limbs

Urinary incontinence (upper motor neuron)

Spinal cord L3-S3

Abnormalities of gait in pelvic limbs only—ipsilateral

Decreased or absent conscious proprioception

Ataxia

Paresis (weakness)

Paralysis

Abnormal spinal reflexes—ipsilateral

Hyporeflexia in pelvic limbs only

Altered muscle tone

Decreased muscle tone in pelvic limbs

Flaccidity of the tail

Urinary incontinence (lower motor neuron)

Fecal incontinence (lower motor neuron)

Peripheral nerve and muscle

Abnormalities of gait

Paresis to paralysis

Decreased or absent conscious proprioception

Ataxia

Paresis (weakness)

Paralysis

Abnormal spinal reflexes—ipsilateral

Hyporeflexia

Altered muscle tone

Decreased muscle tone

Muscle atrophy

Flaccidity of the tail

Urinary incontinence (lower motor neuron)

Fecal incontinence (lower motor neuron)

Table 8-1 Localization of Central Nervous System Lesions According to Major Signs Encountered

Sign or Problem Encountered	Usual Lesion Location
CHANGES IN GAIT AND LOCOMOTION	
Ataxia	Nonspecific; any area of the central nervous system (CNS)
Conscious proprioceptive deficit	Nonspecific; any area of CNS except cerebellum
Knuckling	
Abduction or adduction	
Abnormal postural placement	
Hypermetria	Cerebellum, cerebellar peduncles, spinocerebellar tracts
Circling, or falling to one side	Basal ganglia, cortex, vestibular nuclei, cerebellum
Paraplegia or hemiplegia	Nonspecific
CHANGES IN SENSORIUM AND BEHAVIOR	
Coma or semicoma	Brainstem, thalamus, cortex
Obtundation	Brainstem, thalamus, cortex
Convulsions	Brainstem, thalamus, cortex
Head pressing, propulsive walking	Cortex (frontal lobe), limbic system
Aggression or rage	Limbic system, frontal lobe, amygdala
Inappropriate sexuality	Limbic system
Hyperphagia or hypophagia	Hypothalamus
Diabetes insipidus	Hypothalamus
Head shaking	Unknown, probably peripheral neuropathy
CHANGES IN HEAD POSTURE	
Stiff neck	Meninges, cervical spine
Head tilt	Thalamus, cerebral cortex, medulla, cerebellum
Head tremor	Cerebellum, basal ganglia
Opisthotonos	Cerebellum (rostral vermis), rostral brainstem, cerebrum, cranial nerve VIII
CRANIAL NERVE DYSFUNCTION	
Amaurosis	Cortex, internal capsule, optic chiasm, optic nerve, eye
Anisocoria	Cervical spine, vagosympathetic trunk, mesencephalon (oculomotor nerve nucleus), cranial cervical ganglion, ciliary ganglion, oculomotor nerve
Mydriasis	Oculomotor nerve, brainstem (mesencephalon), eye

Miosis	Vagosympathetic trunk, ciliary ganglia, tectum, brainstem, cervical spinal cord
Ptosis	Facial nerve, vagosympathetic trunk, ciliary ganglion, tectum, brainstem, cervical spinal cord
Strabismus	
Ventrolateral	Cerebellum, vestibular nucleus, oculomotor nerve
Dorsomedial	Trochlear nerve
Medial	Abducent nerve
Nystagmus	
Horizontal	Nerve VII (peripheral)
Vertical or rotatory	Vestibular nuclei, peripheral vestibular receptor, cerebellum, vestibulocochlear nerve
Jaw drop	Metencephalon, trigeminal motor nucleus, trigeminal nerve
Flaccid tongue	Medulla, hypoglossal nerve, hypoglossal nucleus, tongue muscle
Facial paralysis	Medulla, facial nerve, facial muscles
Facial analgesia	Trigeminal nerve (sensory component)
Dry eye	Cranial nerve VII before entering petrous temporal bone
CHANGES IN REFLEXES	
Patellar	L4-L6 spinal cord, femoral nerve, quadriceps femoris muscle
Flexors (forelimbs)	C5-T2 spinal cord segments, radial, ulnar, musculocutaneous and median nerves, and innervated muscles
Flexors (rear limbs)	L6-S2 spinal cord segments (hindlimbs); femoral, ischiatic, peroneal, and tibial nerves; flexor and extensor muscles of the limbs
Triceps	C6-T1 spinal cord segments, radial nerve, triceps muscle
Panniculus	C8 spinal cord segment, thoracodorsal nerve, dorsal column of thoracic spinal cord
Anal	S1-S5 sacral spinal cord segments, pudendal nerve
Ear twitch	Dorsal columns of C1-C3 spinal cord segments; facial nerve, facial nucleus, muscles of ear
Dysuria (dribbling urine)	Spinal cord, pons, pelvic nerves, bladder wall

119

120

The clinical signs of neurologic disease depend on the location of the disease process within the nervous system. Widely varying disease entities may produce similar or identical clinical signs. Seizures, for example, may be the result of metabolic, toxic, traumatic, neoplastic, or other causes. Definitive diagnosis of neurologic disease, therefore, cannot be made on the basis of clinical signs alone. Localization of lesions within the nervous system is the first and key step in developing a differential diagnosis list and a rational diagnostic and therapeutic plan for any animal with signs of neurologic disease. Lesions are localized with the help of the neurologic examination. In this chapter the clinical signs of neurologic disease and the methods and interpretation of the neurologic

examination are described. Fortunately for the veterinarian, the clinical anatomy and the functions of the nervous systems of the various domestic animal species are almost identical. Thus, the clinical signs of neurologic lesions are, for the most part, similar in all these species.

* The authors wish to thank Dr. John W. Schlipf Jr. for his editorial comments.

8.2 DIAGNOSIS OF NEUROLOGIC DISEASES

8.2.1 Signalment

The species, breed, age, and pedigree of an animal are important considerations in the differential diagnosis of neurologic disease. Many diseases are species-specific, particularly in the case of infectious and genetic diseases. Equine protozoal myeloencephalitis, for example, would not be a differential diagnosis in the case of cattle with signs of neurologic disease. Other infectious diseases, such as rabies virus infection, can affect many species. In yet other instances, all species may be affected but may have varying susceptibility to the disease. Such is the case with tetanus caused by *Clostridium tetani* exotoxin; horses and small ruminants are significantly more susceptible to the disease than are cattle. Some diseases not only are species-specific but also have higher incidence in certain breeds of that species. An example of this is equine degenerative myeloencephalopathy, which has been reported in several breeds of horses but has an increased incidence in some breeds, such as the Appaloosa.[1] Examples of the numerous other breed-related neurologic diseases of large animals include cerebellar abiotrophy (Arabian foals), progressive ataxia (Charolais), demyelinating myelopathy (Limousins), neuraxial edema (polled Herefords), neuraxonal dystrophy (Morgans), hydrocephalus (horned Herefords and shorthorns), epileptic seizures and Weaver syndrome (Brown Swiss cattle), ceroid lipofuscinosis (Hampshire sheep), cerebellar abiotrophy, GM1 gangliosidosis (Holsteins), and many others.[2–11] Atlantoaxial malformations most commonly occur in Arabian foals and Holstein calves but are not seen exclusively in those breeds.[12,13]

Disease susceptibility also may be linked to age. Acute lead poisoning, for example, occurs most commonly in calves, whereas adult cattle tend to develop the subacute form of the disease.[14] Some diseases are found in the neonate at birth. A large number of congenital disorders of the central nervous system (CNS) can affect domestic livestock. These diseases have a variable clinical course, depending on the nature of the disorder. Inborn errors of myelin metabolism worsen with age, whereas other developmental conditions may remain stable throughout the animal's life.[15–20] Examples of these disorders are listed in Chapters 51 and 52

A knowledge of the most likely disease entities to occur within individual animals or groups of animals of particular species, breeds, and ages, therefore, can greatly assist the clinician in arriving at a list of likely differential diagnoses and formulating a rational diagnostic and therapeutic plan.

8.2.2 History

Many disorders of the CNS produce characteristic patterns of onset and progression that can have diagnostic importance. Some CNS diseases occur acutely, developing the full range of clinical signs within hours. If the disease is not fatal, the signs either stabilize by 24 hours and remain constant thereafter or improve. Diseases that may display this clinical course include traumatic injuries and some types of toxic, infectious, and metabolic diseases. Diseases with degenerative, neoplastic, and certain viral causes may develop more slowly, requiring days to weeks before the full extent of clinical signs is apparent.[2,21,22]

8.2.3 Diet

The diet of patients with neurologic disease should be evaluated[23–29] (Table 8-2). Common deficiencies of livestock include vitamins A and E, copper, selenium, and magnesium. Vitamin A deficiency occurs in feedlot animals that have no access to green plants; affected cattle become blind and develop seizures. Equine motor neuron disease is seen mainly in horses that are housed without access to pasture and whose diet is deficient in vitamin E.[30] Copper deficiency occurs in ruminants pastured in areas with shale or volcanic soils, which either are deficient in copper or contain high concentrations of molybdenum and sulfur (secondary copper deficiency). The deficiency produces demyelination of the spinal cord in lambs and kids and pathologic fractures of the lumbar spine of rapidly growing calves. Dietary deficiency of calcium in rapidly growing weaned calves also results in vertebral and long bone fractures. Although dietary deficiencies of vital nutrients are commonly associated with the development of neurologic diseases, oversupplementation of certain nutrients also may produce neurologic disorders. Overfeeding of calcium, micronutrient imbalance, protein, and energy to horses, for instance, has been linked to the development of cervical vertebral instability and stenosis (wobbler syndrome) in horses.[31,32]

Table 8-2 Dietary Deficiencies Associated with Neurologic Disorders of Livestock

Dietary Deficiency	Disease Produced	Neurologic Sign
Copper	Demyelination, pathologic fractures of vertebrae	Ataxia, recumbency
Vitamin E	Demyelination	Ataxia, recumbency
Vitamin A	Encephalopathy	Convulsions, blindness
Magnesium	Grass tetany, transport tetany, milk tremors	Convulsions, tremors, ataxia
Potassium	Weakness	Postpartum recumbency
Calcium or phosphorus	Milk fever, pathologic vertebral fractures, tetany	Weakness, ataxia, recumbency, tetany
Vitamin E or selenium	Nutritional myodegeneration	Weakness, ataxia, recumbency, acute death

120

121

8.2.4 Environment

Examination of the patient's environment may provide valuable information about the cause of CNS disease. Outbreaks of botulism and listeriosis have been associated with ingestion of rotting vegetation around haystacks, silos, and feed bunks.[33,34] Plant poisonings are common in livestock, and identification of neurotoxic plants is important whenever multiple animals are affected simultaneously.[34–36] (Table 8-3). Clinical signs of plant poisonings are variable and may include ataxia, hypermetria, head tremors, convulsions, paralysis, coma, or sudden death. Nonplant neurointoxicants of livestock include lead, ethylene glycol, organic mercurials, chlorinated hydrocarbons, organophosphates, salt, sulfur, petroleum distillates, and many others. Dose of the neurointoxicant may be important, with different clinical signs appearing depending on the level of exposure.

Ingestion of high concentrations of organophosphates or carbamates inhibits cholinesterase and produces signs of parasympathetic and neuromuscular activation, including marked ataxia, coma, muscle tremors, salivation, and miotic pupils. When low doses of organophosphates are ingested chronically, however, the result is an axonopathy of spinal cord and medullary neurons. The clinical signs that result are predominantly those of hindlimb paresis and ataxia, which may progress to tetraparesis and recumbency.[37] Ingestion of petroleum distillates (motor oil, gasoline, kerosene) by cattle can induce narcosis. Some petroleum distillates also may contain toxic concentrations of lead. Other sources of lead include paints, batteries, waste dumps, and smelters. Therapeutic and dietary interventions also may result in toxicoses when improperly administered. Overtreatment of cattle with propylene glycol produces profound ataxia, depression, and coma. Ingestion of ammonia or ammoniated feedstuff produces hyperesthesia, excitability, coma, and convulsions. High concentrations of salt in drinking water or, more commonly, lack of fresh water or interruption of the water supply followed by unlimited access to water, can result in laminar necrosis of the cerebral cortex or eosinophilic meningitis.[37] The clinical signs are those of cerebral dysfunction, including blindness, dullness, seizures, coma, and death. Although this syndrome has been reported in cattle and sheep,[38–40] pigs seem to be particularly susceptible.

Table 8-3 Poisonous Plants Producing Neurologic Signs (Also See Chapter 54)

Plant Poisoning	Clinical Signs
Bermuda grass *(Cynodon dactylon)*	Ataxia, head tremors, spasms, recumbency
Water hemlock *(Cicuta maculata)*	Tremors, vomiting, ataxia, sudden death, convulsions, odontoprisis, pupillary dilation, abortions, bloat
Poison hemlock *(Conium maculatum)*	Tremors, vomiting, ataxia, sudden death, abortions, pupillary dilation, bradycardia, coma
Blue green algae *(Aphanizomenon, Anabaena flos-aquae)*	Sudden death, tremors, salivation, miosis, bradycardia
Laburnum *(Laburnum anagyroides)*	Excitement, incoordination, convulsions, death
Milkweed (*Asclepias* species)	Tremors, salivation, ataxia
Larkspur *(Delphinium)*	Ataxia, collapse, recumbency, inability to lift head, tremors of face, flank, and hip; vomiting
Ryegrass ergot *(Claviceps paspali)*	Ataxia, head tremors, truncal ataxia, spasms, recumbency
Tobacco (*Nicotiana* species)	Tremors, salivation, ataxia, convulsions, birth defects
Nightshades (*Atropa* species, *Solanum* species)	Tremors, ataxia, recumbency, convulsions
Monkshood *(Aconitum)*	Restlessness, salivation, paresthesia, irregular heartbeat, recumbency, coma
Locoweed (*Astragalus* species)	Ataxia, weight loss, recumbency, hyperesthesia
White snakeroot *(Eupatorium rugosum)*	Tremors, salivation, convulsions
Rayless goldenrod *(Haplopappus heterophyllus)*	Lassitude, obtundation, arched back, stiff-legged gait, tremors, weakness, collapse
Bracken fern *(Pteridium aquilinum)*	Ataxia, weight loss, strip sweating (horses only)
Horse tail *(Equisetum arvense)*	Ataxia, weight loss, strip sweating (horses only)
Yellow star thistle *(Centaurea solstitialis)*	Facial rigidity, lack of prehension, ataxia, depression (horses only)
Tansy ragwort *(Senecio jacobea)* and groundsel *(Senecio vulgaris)*	Ataxia, obtundation, somnolence, excitability, head pressing (hepatic encephalopathy)
Fiddleneck *(Amsinckia intermedia)*	Ataxia, obtundation, somnolence, excitability, head pressing (hepatic encephalopathy)
Rattlebox *(Crotalaria spectabilis)*	Ataxia, obtundation, somnolence, excitability, head pressing (hepatic encephalopathy)
Death camus (*Zigadenus* species)	Trembling, uncontrolled running, recumbency, opisthotonos, convulsions, vomiting, salivation
Dutchman's breeches *(Dicentra)*	Trembling, uncontrolled running, recumbency, opisthotonos
Buckeye (*Aesculus* species)	Incoordination, twitching, sluggishness
Rape *(Brassica napus)*	Blindness, ataxia, aggressiveness

Cheesewood *(Malva)*	Tremors, worsened by forced exercise, hyperflexion of the hock during movement (stringhalt)
Lupine *(Lupinus)*	Tremors, hyperexcitability, depression
Dandelion *(Taraxacum officinale)*	Hyperflexion of the hock during movement (stringhalt)

Geographic area also may be important in the differential diagnosis of neurologic disease. Certain infectious diseases may be more common in particular areas of the country or even regions within a single state where the conditions for disease vectors are optimal.[41] The travel history of the animal must be considered, as well as the animal's location at the time clinical signs appeared. Travel also may result in increased contact with other animals and greater risk of exposure to infectious diseases. Recent movement of animals onto the premises may be important with respect to the likelihood of infectious diseases such as equine herpesvirus 1 and equine infectious anemia. 121 122

8.2.5 Vaccination and Disease History

When a neurologic problem is evaluated, the vaccination history and previous herd or individual disease problems should be noted. Some vaccines are highly protective, whereas others are less so. Examples of effective vaccines include those for focal symmetric encephalomalacia (enterotoxemia caused by *Clostridium perfringens* type D), rabies, and tetanus. Neurologic disease may be a secondary complication of disease in another organ system. Foals and calves with severe diarrhea, for example, may convulse secondary to hypokalemia, hypernatremia, or hypoglycemia. Preexisting diseases or clinical syndromes should be determined. For example, outbreaks of the CNS form of equine herpesvirus I are often preceded by respiratory disease or abortions in herdmates. Thromboembolic meningoencephalitis of cattle often follows an outbreak of respiratory disease within the herd. Historical evidence of limited colostral intake may be important in the diagnosis of bacterial meningitis of neonates. Bloody diarrhea often precedes the onset of nervous coccidiosis of calves.

8.2.6 Gestational Stage

Hypomagnesemia, eclampsia (hypocalcemia), hypokalemia syndrome, hypophosphatemia (postparturient hemoglobinuria) and nervous ketosis are common causes of recumbency, convulsions, and tremors in adult livestock. These diseases usually occur between the end of the last trimester and the first 2 months after parturition.

8.3 NERVOUS SYSTEM EXAMINATION

8.3.1 General Comments

A thorough physical examination should always precede or be performed concurrently with the neurologic examination. Physical examination may reveal evidence of systemic disease that underlies the neurologic problem—for example, icterus in animals with liver disease resulting in hepatic encephalopathy, unthriftiness in animals on poor diets, or traumatic injuries. In some instances disease of organ systems other than the nervous system may take precedence for diagnosis and treatment. Such may be the case with animals in shock or suffering from other life-threatening cardiovascular or respiratory disturbances. A common practice is to perform a general physical examination followed by a neurologic examination, but many aspects of nervous system

function, such as assessment of mental status and cranial nerve examination, may be carried out during the physical examination.

The neurologic examination should be carried out in a systematic fashion. The exact order of the examination is not important in itself, but procedures that may cause discomfort or pain, such as palpation of the spine, should be left until last. A common system used by many neurologists is to start at the head and progress to the tail.[42] This system is very useful in small animals but may be less so in large animals. Some clinicians prefer to examine the animal standing in the stall initially, then observe the gait. Because large animals are less amenable to handling than the typical cat or dog, another system for the neurologic examination is to begin with procedures that require minimal handling of the animal, such as observation of mental status, posture, and gait, and proceed to those that require greater manipulation: examination of the cranial nerves, assessment of spinal reflexes, and so on. The latter is the system that is described in the following sections. Each individual should develop a system that is effective for him or her, bearing in mind that one goal of the neurologic examination is to induce as little stress in the animal as possible because stress may alter the results of the examination.

Neurologic examination alone rarely leads to definitive diagnosis, but rather helps to answer the questions “Does the animal have neurologic disease?” and “What is the location of the neurologic lesion?” Once these questions are answered, a list of differential diagnoses can be made in light of other information such as the signalment of the animal and the history of the current problem. The diagnostic plan is based on the location of the lesion and the most likely differential diagnoses.

8.3.2 Mentation and Behavior

Initial examination should be done from a distance. The examiner observes the animal's mental state and whether its responses to its surroundings are appropriate. This is done ideally in the animal's usual environment, where it would be expected to be most calm. When this is not possible, the influence of factors such as the stress and excitement of previous travel and the animal's natural fear of unfamiliar surroundings, sounds, and smells must be taken into account. The reports from the animal's usual handler may be informative, if he or she is a good observer and has an understanding of normal behavior in animals. Compare the patient's interaction with its environment to a summary of its previous behavior and to the activities of the herdmates. Normal animals respond to mild stimulation. Most normal animals actively seek food when offered but vigorously avoid needle pricks. All livestock should recognize and fear strangers and should show awareness of the examiner's position. Normal animals change the posture of the head, ears, and eyes as the examiner moves. Depending on previous conditioning, normal behavior may include cautionary moves, avoidance, belligerence, or affection. Animals with decreased mental awareness (obtunded, dull, depressed) have reduced responses that may include lassitude, lack of recognition, unwillingness to rise or lift the head from the ground, head pressing, propulsive walking, lack of appetite, drooped ears, convulsions, stupor, or coma (Fig. 8-1). Systemic illness also may cause dull mentation; thorough physical examination and, perhaps, diagnostic tests including a complete blood count and serum chemistry are important in determining whether systemic disease is present. Furthermore, animals with primary CNS disease tend to have more profound dullness than do those with systemic disease alone. Hyperexcitability, rage, mania, or frantic motor activities are suggestive of a lesion of the limbic system, an assembly of connected groups of neurons (nuclei) and neuronal tracts in the cerebrum, thalamus, hypothalamus, and midbrain that is involved in emotional responses and patterns of behavior. Such animals may strike or kick at inappropriate times, demolish their stalls, bellow, show belligerence, or, if recumbent, struggle violently. The age, species, previous management system, and even the breed of animal are important considerations in the assessment of behavior. Bulls and stallions exhibit behavior that is very different from that of steers and geldings. Beef cattle behave differently than dairy cattle do. Animals that are handled regularly show fewer and milder fearful or aggressive responses than do animals that are handled rarely.

Fig. 8-1 Dull mentation in a horse with cerebral toxicosis caused by sage toxicity (Salvia species).

Changes in mental status are consequences of disease affecting either the cerebrum or the ascending reticular activating system (ARAS). The cerebral cortex is the “seat of consciousness”: conscious perception of both external stimuli (e.g., vision, hearing, touch) and internal stimuli (e.g., abdominal pain) depends on the integrity of the cerebral cortex. Both primary intracranial diseases (e.g., encephalitis, traumatic injury) and extracranial diseases (e.g., metabolic derangements, toxicities) can alter the functions of the cerebral cortex.

The ARAS is composed of a number of neuronal pathways that lie centrally within the brainstem (medulla oblongata, midbrain, and thalamus). The ARAS receives collateral input from all sensory information reaching

the brain, which it conveys ultimately to the cerebral cortex, where it reaches the level of consciousness. The ARAS is important in maintaining the animal's level of consciousness and arousal. The relationship between the cerebral cortex and the ARAS is sometimes described as follows: the cerebral cortex determines the content of consciousness, and the ARAS determines the level of consciousness. Diseases affecting the ARAS tend to produce more profound depression of consciousness, such as coma, than do those affecting the cerebral cortex alone, although this is not an absolute rule. Lesions of the ARAS occur commonly within the midbrain segment of this system, so that other signs of midbrain disease, such as pupillary dilation and loss of the oculocephalic reflexes (see below), often are observed in animals with lesions of the ARAS.

A seizure (convulsion, ictus) is a manifestation of cerebral cortex dysfunction characterized by loss of consciousness or involuntary motor activities. Seizures may be generalized or focal (partial). Generalized seizures are characterized by loss of consciousness and variable degrees of involuntary motor activity, which may include flailing of the limbs, elimination of feces and urine, and nystagmus. Localized involuntary movements with or without obvious alterations of consciousness characterize focal seizures. Alternatively, focal seizures may result in episodes of abnormal or bizarre behavior or momentary lapses of consciousness without collapse or significant motor activity. A third form of seizure is focal with secondary generalization. The onset of the seizure is focal, but seizure activity subsequently spreads throughout the cerebral cortex, resulting in a generalized seizure. Animals with this form of seizure activity exhibit initial focal signs, such as head turning, bellowing, focal tremors, and so on, followed by loss of consciousness and generalized signs of involuntary motor activity, as described previously. In most animals with focal seizures, with or without secondary generalization, the outward manifestation of the seizure is always the same. Rarely, seizures may be preceded by an aura, a period in which the animal exhibits anxiety or restless behavior shortly before the onset of the seizure itself. In most cases of seizures in animals, however, an aura is not observed. A postictal phase, a period of time subsequent to the seizure during which the animal exhibits abnormal behavior such as lethargy, restlessness, or anxiety, is usual after seizures in most animals. The postictal phase usually lasts a few minutes to hours but may last as long as several days. The postictal phase may be the only stage of the seizure observed by the animal's handler. Thus, any animal with a history of episodes of abnormal behavior should be suspected of having seizures. The typical history is that the animal is found in a dull or excited state, without the handler observing the onset of this change of behavior. Additional supporting evidence includes physical injuries such as scrapes and cuts that may have been incurred during the seizure itself.

Abnormalities of cerebral cortex dysfunction are the ultimate cause of seizure activity. During a seizure, groups of neurons in the cerebral cortex exhibit spontaneous electrical activity resulting in the clinical manifestations of focal or generalized seizures. Whereas neurons in the cerebral cortex ultimately become involved, abnormal electrical activity can begin elsewhere in the brain, such as in the brainstem, with subsequent spread of this activity to the cerebrum. Causes of seizures are legion, including alterations in the neuronal environment resulting from metabolic disturbances or toxicities, and the effects of structural brain diseases such as congenital or developmental disorders, traumatic injuries, neoplasia, and inflammatory conditions. Diagnosis of seizures and other states of altered mentation must include a thorough physical examination and screening for metabolic diseases such as electrolyte imbalances and hepatic or renal failure.

Abnormalities in the neurologic examination found between seizures (interictal period) support a diagnosis of primary brain disease and are an indication for diagnostic procedures such as cerebrospinal fluid (CSF) tap. Some toxins cause systemic signs as well as seizures, such as neuromuscular involvement (tremors, weakness) or parenchymal organ failure (icterus, uremia). Such signs, combined with a good clinical history and complete examination of the animal's environment, will help to direct specific toxicologic screening tests.

Narcolepsy is a condition wherein the normal mechanisms of sleep are disturbed. Although sudden onset of rapid eye movement (REM) sleep is one manifestation of narcolepsy, the acute onset of cataplexy—complete paralysis of striated muscles—usually is a more prominent clinical feature. Animals may be observed to suddenly collapse to the ground or to buckle at the knees. Cardiac and respiratory muscles are not affected. Narcoleptic attacks may be difficult to distinguish from seizures but are not accompanied by the involuntary motor activity that characterizes most generalized seizures. In some cases owners observe traumatic injuries to the head, face, and limbs without observing the cataplectic attacks that cause the trauma. Narcolepsy has been reported both in cattle and horses.[43–46]

123

124

8.3.3 Gait

Gait should be evaluated by moving the animal in a straight line, moving it in a tight circle, backing up, and moving it over obstacles such as a curb. Having the patient walk up and down a slope with varying steepness and with the head elevated may reveal more subtle abnormalities. The examination may need to be modified depending on the species of the patient, amenability to handling, and consideration of safety concerns. In general, horses are more tolerant of handling than are ruminants.

Quadrupeds begin walking by protracting the rear limb, followed by the forelimb of the same side, then the opposite rear limb, and finally the opposite forelimb. Gait on a level surface requires integrity of the musculature, motor and sensory components of the peripheral nerves, local spinal reflexes, ascending and descending pathways in the spinal cord, and centers within the brainstem. Dysfunction of any of these areas results in an animal with mild to severe proprioceptive disturbances when standing or walking, which are exacerbated by turning the animal in a circle or stepping it on and off a curb. Animals with cerebral disease usually are able to perform simple motor activities such as walking along a straight path without obvious deficits but exhibit decreased proprioception when they are required to perform complex motor activities, such as walking on slopes or negotiating obstacles such as curbs or ground poles. Performance of such complex maneuvers requires coordination of proprioception and motor activities within the cerebral cortex, basal nuclei, and other CNS centers. Subtle deficits may be elicited by walking and then trotting the patient, or walking or trotting the patient briskly and then stopping suddenly. While a helper is walking the animal in a straight line on a level surface, the examiner should take hold of the tail and pull the animal sharply to one side. The normal animal will move toward the pull but should not stumble or fall. If the tension on the tail is maintained, strength can be assessed. Animals with lesions anywhere within the ascending or descending pathways controlling gait may show decreased proprioception in the form of stumbling, tripping, or crossing the limbs or may be weak. This maneuver also is useful for assessing the symmetry of a lesion. Circling the patient in a wide circle and then a tight circle also may elicit deficits, such as knuckling, stumbling, interference between feet, pivoting on one foot, or wide movements in the outside limb, that are not observed when the animal is walked in a straight line. Assessment of gait is facilitated when animals are halter-broken and can be lead. This is not the case in many ruminants, so the clinician must rely more on observing the animal in its usual environment or in a confined area such as a pen. A handler may drive animals that are not halter-broken, but this should be done with caution; safety of the animal and handler must be the top priority.

A grading system for gait deficits has been described elsewhere,[47] as follows:

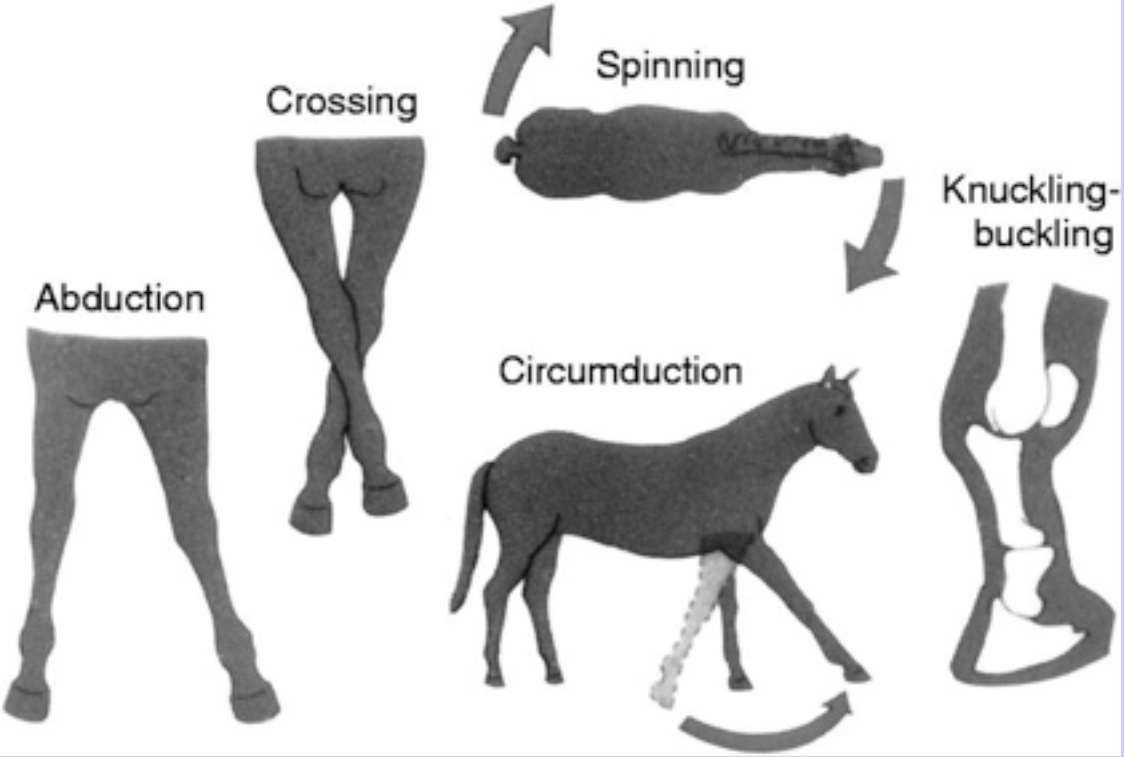
Grade 0:	Normal gait
Grade 1:	Very subtle deficits, observed by only an experienced clinician
Grade 2:	Deficits apparent to an inexperienced clinician
Grade 3:	Deficits apparent to laypersons
Grade 4:	Severe deficits, including stumbling, knuckling at the fetlock, falling
Grade 5:	Recumbency and inability to rise

Proprioception is the sense of position in space. Receptors lie in the skin, joints, and muscles. Ascending pathways run mainly in the dorsal funiculus of the spinal cord, relaying information to centers in the brainstem and cerebral cortex. Descending pathways involved in proprioception are largely similar to those that control gait. The vestibular system and pathways in the spinal cord to and from the vestibular centers in the medulla oblongata and cerebellum also help to control proprioception. Abnormalities of proprioception include knuckling, stumbling, adduction or abduction of the limbs, circumduction, and interference between limbs (Fig. 8-2). Animals with proprioceptive deficits often slap down the feet hard, rather like the gait of a person walking down stairs in the dark, unsure of where the next step is. Walking the animal off a curb or step exaggerates this appearance. When spun in a tight circle, normal animals lift the inside forefoot as the weight shifts. The outside rear leg is put down within a line demarcated by the lateral margin of the trunk. When spun in a tight circle, patients with abnormal proprioception may pivot on the inner forefoot rather than lifting it and replacing it into a normal position. The outside foot may circumduct widely, knuckle, or buckle, and the inside foot may step on the outside foot. Animals with abnormal proprioception worsen when they are required to climb hills or lift the foot over a curb or are walked with the head elevated. The gait of noncompliant cattle may be assessed by observation of maneuvers through corrals, alleys, or a squeeze chute.

Having the animal walk backward tests strength and proprioceptive function further. The normal subject should be able to do so in a smooth, coordinated fashion. Animals with lesions of either the ascending or descending motor pathways may exhibit abnormalities such as foot dragging and weakness, sometimes to the point of “dog-sitting.” Otherwise cooperative animals may be reluctant to move straight backward and will try avoidance maneuvers such as circling to one side or the other in order to avoid it. Such tactics should raise the index of suspicion of a neurologic deficit. Care should be taken when backing an animal with severe neurologic deficits because some animals could fall backward during the procedure. Animals that are uncooperative or that have been little handled may exhibit reluctance to walk backward that is not caused by neurologic disease. Observing the patient's general level of cooperation and having a good history will help the examiner determine whether the problem is caused by neurologic disease or is the result of the animal's lack of compliance.

Cerebellar disease causes generalized ataxia with a rolling, drunken gait. Protraction of the limbs is delayed and limb movements are exaggerated, a condition known as hypermetria. This is often accompanied by opisthotonos, which is a hyperextension of the head and neck, and intention tremor, most easily observed in the head. 124
Purposeful movements, such as reaching out to take food, exaggerate intention tremor, and muscular relaxation, 125
as in a recumbent animal, eliminates it.

Fig. 8-2 Examples of conscious proprioceptive deficits in a horse. The signs of proprioceptive deficits in ruminants are similar.



Spontaneous circling is seen in diseases of the vestibular system, midbrain, and cerebrum. Circling varies from a mild tendency to circle in one direction to tight and compulsive circling, seen particularly with midbrain disease. Circling occurs toward the side of the lesion, except in paradoxic vestibular disease (caused by lesions in the vestibular components of the cerebellum), in which the animal circles away from the side of the lesion. Localization of the neurologic lesion in animals that circle is made on the basis of other neurologic abnormalities, such as the state of consciousness, the presence of proprioceptive deficits, and the presence of signs such as head tilt, spontaneous nystagmus, seizures, or abnormal ocular function.

8.3.4

Conscious Proprioception and Postural Reactions

The integrity of conscious proprioceptive pathways may be tested by means of the postural reactions. Normal animals stand at rest with the limbs in line with the abaxial boundaries of the trunk. When the limbs are moved, normal animals do not permit the limbs to be placed outside of the body axis or across midline. After placement of the limbs in an abnormal position, the neurologically intact animal returns to a normal stance within a few seconds. Animals with conscious proprioceptive deficits allow the limb to remain in the abnormal position for longer than the usual period of time. This can vary from animals in which replacement of the limb into a normal position is slightly slowed to animals that do not try to replace the limb at all. The examiner should cross one of the animal's limbs over the opposite limb, or abduct one limb; the normal response is for the limb to be placed back into the resting position. Normal animals often strongly resist attempts to place the limbs in abnormal

positions. Animals with proprioceptive deficits may spontaneously place the limbs in abnormal positions: excessively adducted, abducted, or even crossed. Abnormalities of proprioception alone are poorly localizing signs, although a couple of generalities may be stated. Unilateral lesions rostral to the medulla oblongata produce mild to moderate proprioceptive and postural deficits in the contralateral limbs. Unilateral lesions in the medulla oblongata or spinal cord produce more severe proprioceptive and postural deficits in the ipsilateral limbs. Lesions of the cerebellum very rarely result in postural deficits.

Additional postural reactions, such as hopping and hemiwalking, can be tested in small ruminants, calves, and some foals. Hopping is tested in the forelimbs by lifting the rear limbs a few inches off the ground by means of a hand and arm placed around the abdomen, flexing one forelimb slightly, and moving the animal away from the side of the flexed forelimb, so that it has to hop laterally on the forelimb still in contact with the ground. It is easiest if the examiner stands in one place and turns clockwise when testing the animal's right forelimb and counterclockwise when testing the left forelimb. Hopping in the rear limbs can be tested similarly, supporting both forelimbs off the ground with an arm around the chest. Hemiwalking is done by supporting both limbs on one side of the body in a slightly flexed position and pushing the animal toward the opposite side so that it must walk laterally on the two limbs still in contact with the ground. Both hopping and hemiwalking should be done with care not to push the patient over. Hopping and hemiwalking involve the same ascending and descending motor tracts involved in gait on a level surface but also require integrity of the cerebral cortex. These maneuvers are abnormal on the ipsilateral side in animals with lesions in the skeletal muscles, peripheral nerves, spinal cord, and medulla oblongata and on the contralateral side in animals with lesions in the midbrain, thalamus, or cerebrum. Animals with cerebral lesions have normal gait on a level surface, but marked deficits in hemiwalking and hopping.

8.3.5 Abnormalities of Posture and the Righting Response

Posture refers to the position of the body and head in space, in relationship to gravity and to each other. Animals adopt slightly different postures when on a sloped surface or an uneven surface compared with posture on a level surface. However, sustained postures such as head tilt (Fig. 8-3), in which one ear is closer to the ground than the other, and head turn (Fig. 8-4), in which the muzzle is turned back toward the trunk, are abnormal. Circling often accompanies head tilt and head turn, and all tend to be toward the direction of the lesion. The exception to this rule occurs in paradoxic vestibular syndrome as a result of involvement of the cerebellar components of the vestibular system, in which head tilt and circling occur in the direction away from the side of the lesion. When proprioceptive deficits accompany circling they are ipsilateral when the lesion is in the medulla oblongata and contralateral when the lesion lies in the cerebrum, thalamus, or midbrain. Head tilt, head turn, and circling reflect the presence of lesions that are unilateral within the neuraxis or are asymmetric.

The righting response is most easily tested in small ruminants and in recumbent large animals (Fig. 8-5). The response is initiated by receptors in the eyes and vestibular labyrinths and by proprioceptive receptors in the joints, tendons, and muscles. Information regarding limb position and balance is relayed ultimately to the cerebral cortex. Descending impulses are initiated in the motor cortex and relayed via the brainstem and spinal cord to the appendicular musculature. The normal response to stimulation is to lift the head, assume sternal recumbency, and rise. The normal horse rises on the forelimbs first, whereas the normal ruminant rises on the rear limbs first. Animals that are reluctant to rise but do so normally after sufficient stimulation may have a disease of the cerebral cortex or the thalamus. Animals that are in lateral recumbency and unable to lift the head from the ground may have lesions in the peripheral or brainstem vestibular centers or in the cervical spinal cord proximal to the C4 spinal cord segment. Unilateral lesions in this area result in an inability to lift the head from the ground when the lesion side is up. When the lesion side is down, the animal can raise the head slightly. Animals with incomplete lesions of the cervicothoracic spinal cord (C7 to T1 spinal cord segments) are able to

125

126

lift the head and neck but may remain recumbent. Animals with lesions of the thoracolumbar and lumbosacral spinal cord (T3 to S3 spinal cord segments) usually can lift the head and neck, arise on the forelimbs, and assume a dog-sitting position when stimulated.

8.3.6 Spinal Reflexes

The spinal reflexes are stereotyped responses to specific stimuli. They include the myotactic or tendon reflexes, the panniculus or cutaneous trunci reflex, the perineal reflex, and several others. As their name implies, spinal reflexes depend on the integrity of local spinal cord segments, as well as the peripheral nerves, neuromuscular junctions, and muscles. Lesions in the spinal cord that are located rostral to the spinal origin of the peripheral nerves to the limbs being tested result in normal to increased spinal reflexes and are commonly referred to as *upper motor neuron lesions*. Lesions in the spinal cord segments at the level of the reflex arc or in the peripheral nerves, neuromuscular junctions, or muscles result in decreased spinal reflexes and are commonly referred to as *lower motor neuron lesions*.

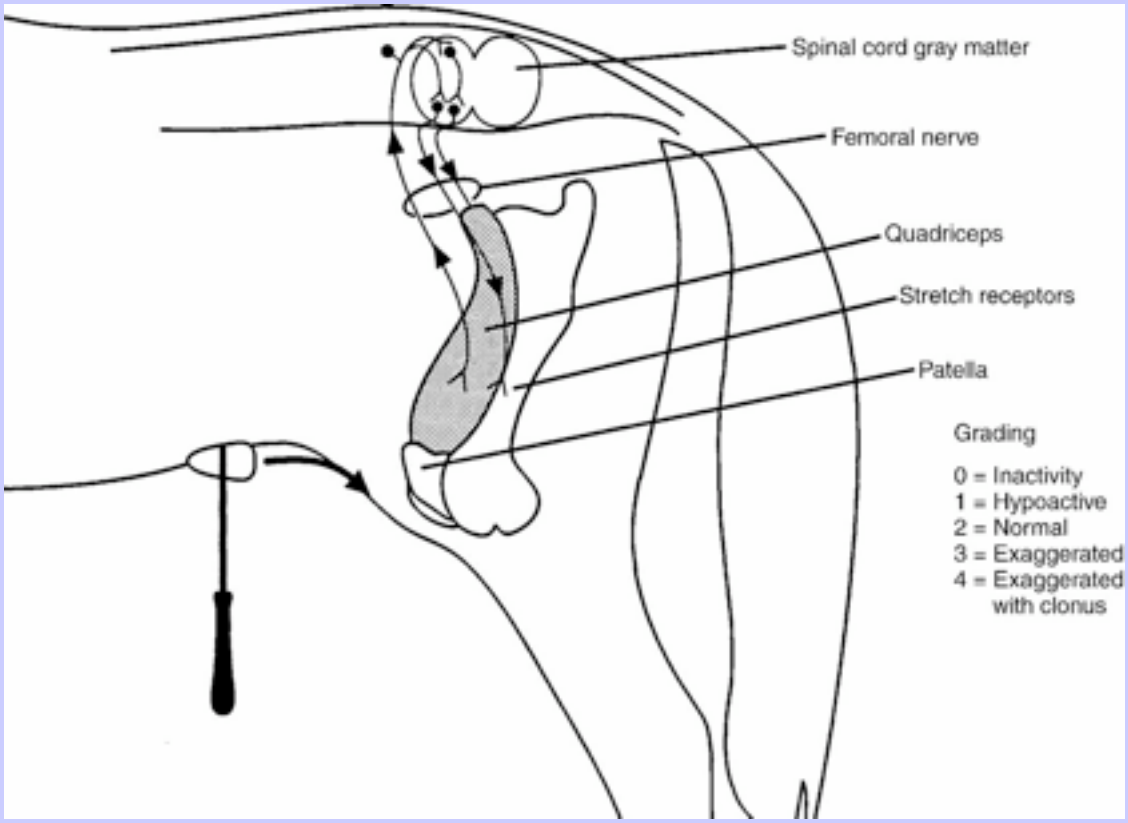
It is appropriate at this point to define the terms *upper motor neuron* and *lower motor neuron*. Upper motor neurons are nerve cells whose cell bodies lie within the brain and whose axons terminate at synapses within the brain or in the spinal cord. Disease affecting upper motor neurons results in normal to increased spinal reflexes, as well as ataxia, variable severity of weakness, and sometimes increased muscle tone (spasticity). The nerve cell bodies of lower motor neurons lie in the nuclei of cranial nerves in the brainstem or within the ventral horn gray matter of the spinal cord. Their axons project beyond the CNS, course within the peripheral or cranial nerves, and terminate at neuromuscular junctions. Diseases affecting lower motor neurons result in decreased spinal reflexes, ataxia, moderate to severe weakness, decreased muscle tone, and rapid, pronounced atrophy of the denervated muscles.

8.3.7 Myotactic Reflexes

Myotactic or tendon reflexes are tested by sharply striking the tendon of a specific muscle (or sometimes the muscle itself) and evaluating the strength of the reflex contraction. The ascending component of the reflex arc involves the muscle spindles, which are stretch detectors, sensory fibers in the peripheral nerve, the dorsal nerve root and its ganglion, and the central projection of the sensory nerve fiber onto the ventral horn cell in the same spinal cord segment (Fig. 8-6). The descending component of the reflex arc involves the ventral horn cell (lower motor neuron), the ventral nerve root, the motor fibers in the peripheral nerve, the neuromuscular junction, and the myofibers in the muscle being tested. Lesions in either the ascending or descending components of the reflex arc result in a decreased to absent myotactic reflex. Lesions in the spinal cord above the level of the reflex arc and lesions of the brain result in a normal to increased myotactic reflex.

126
127

Fig. 8-6 Pathways governing patellar tendon reflex.



The myotactic reflexes can be tested only in the recumbent animal and thus are able to be examined only in a limited number of large animal patients. These reflexes should be tested only in the limbs that are uppermost when the animal is lying on one side. The animal must be turned over to test the limbs on the opposite side. These reflex responses are more subtle than in small animals and may not be elicited in some normal patients. The reflex responses are assigned a qualitative clinical score. One common classification is as follows:

0—No reflex activity

1—Hypoactive

2—Normal

3—Hyperactive

4—Hyperactive and clonic

Clonus is a phenomenon observed with severe upper motor neuron lesions: the response of the muscle being tested is rapid, repeated contractions rather than a single contraction. The innervation of the limbs is listed in Tables 8-4 and 8-5.

8.3.7.1 FORELIMB MYOTACTIC REFLEXES

8.3.7.1.1 Triceps Reflex

Hold the limb moderately flexed at the elbow, and percuss the triceps tendon just above the olecranon using a heavy instrument, such as a balling gun. In smaller subjects a rubber pleximeter can be used, as is done in cats and dogs. The normal response is a contraction of the triceps muscle, leading to retraction of the upper limb and extension of the elbow. The triceps reflex measures the integrity of the radial nerve and the C7 to T1 spinal segments.

Table 8-4 Innervation of the Forelimbs of Large Animals

Spinal Cord Segment	Peripheral Nerve	Muscle(s)
C7	Suprascapular	Supraspinatus, infraspinatus
C6, C7	Subscapular	Subscapularis
C7, C8, T1	Pectoral	Subscapularis, pectoral muscles
C6*, C7, C8	Musculocutaneous	Biceps brachii, coracobrachialis, brachialis
C8, T1, T2	Median	Flexor carpi radialis, deep digital flexor, superficial digital flexor
C8*, T1, T2	Ulnar	Flexor carpi ulnaris, deep digital flexor, superficial digital flexor
C7, C8, T1	Radial	Triceps, extensor carpi radialis, ulnaris lateralis, lateral and common digital extensors
C6†, C7, C8	Axillary	Deltoideus, teres minor, subscapularis, cleidobrachialis
C7, C8	Long thoracic	Serratus ventralis
C8, T1, T2†	Thoracodorsal	Latissimus dorsi
C8, T1, T2	Lateral thoracic	Panniculus

* Contributes innervation in the ruminant only.

† Contributes innervation in the horse only.

Table 8-5 Innervation of the Hindlimbs of Large Animals

Spinal Cord Segment	Peripheral Nerve	Muscle(s)
L3*, L4, L5, L6†	Femoral	Quadriceps
L5*, L6, S1	Cranial gluteal	Gluteals, tensor fascia latae
S1-S5	Caudal gluteal, pudendal	Biceps femoris, middle and superficial gluteals
L5*, L6, S1, S2	Ischiatic, fibular	Lateral digital extensor, long digital extensor, short digital extensor, cranial tibial
L5*, L6, S1, S2	Tibial	Gastrocnemius, popliteus, superficial and deep digital flexor, interosseus
L5*, L6, S1, S2	Pudendal	Retractor penis
S3-Cd5	Caudal rectal	Rectum, anal sphincter, bladder

* Contributes innervation in the horse only.

† Contributes innervation in the ruminant only.

8.3.7.1.2

Biceps Reflex

Hold the limb moderately extended at the elbow and place the supporting hand over the attachment of the biceps muscle on the dorsomedial aspect of the limb at the level of the elbow joint. Percuss the biceps tendon or the taut biceps muscle with a heavy instrument. Contraction of the muscle may be perceived visually or by palpation. A slight flexion of the elbow and extension of the carpus is normal. The test measures the function of the musculocutaneous nerve and spinal cord segments C6 to C8 in ruminants and C7 and C8 in horses.

Lesions rostral to C6 result in general hyperreflexia of both forelimbs and hindlimbs. Lesions located in spinal segments C5 to T2 result in hyporeflexia to areflexia of the forelimbs and hyperreflexia of the hindlimbs.

8.3.7.2

REAR LIMB MYOTACTIC REFLEXES

8.3.7.2.1

Patellar (Quadriceps) Reflex

Flex the stifle moderately, and sharply percuss the middle patellar ligament with a heavy instrument, or a rubber pleximeter in smaller subjects. The normal reflex is a sharp contraction of the quadriceps femoris muscle resulting in extension of the stifle and a forward jerk of the lower limb. The patellar reflex measures the function of the femoral nerve, the quadriceps femoris muscle, and L3 to L5 and L4 to L6 spinal cord segments in the horse and cow, respectively.

8.3.7.2.2 Cranial Tibial Reflex

The cranial tibial reflex is elicited by flexing the hock and sharply striking the belly of the cranial tibial muscle. The reflex consists of a slight extension of the digit. The cranial tibial reflex is mediated through the peroneal and sciatic nerves and spinal cord segments L5 to S2 or L6 to S2 in the horse and the ruminant, respectively. Lesions of the spinal cord anterior to L3 segments result in hyperreflexia, whereas lesions of L3 to L6 spinal segments result in hyporeflexia or areflexia.

The reflex part of the test measures the function of the peroneal, tibial, and sciatic nerves and the function of L6 to S2 spinal segments. The peroneal nerve supplies cutaneous innervation to the dorsolateral aspect of the limb. The tibial nerve supplies innervation to the caudomedial and dorsomedial aspects of the limb.

8.3.8 Flexor Reflexes

The flexor reflexes are elicited in the recumbent large animal. A painful stimulus is applied to the uppermost foot. The normal reflex consists of two phases: (1) a rapid limb flexion, and (2) a slower conscious perception of the stimulus, characterized by attempts to assume sternal recumbency, vocalization, ear and eye movements, violent kicking, and so on. The forelimb flexor reflex tests the integrity of the axillary, median, and musculocutaneous nerves and spinal cord segments C5 through T2, as well as the flexor muscles of the limb. The hindlimb flexor reflex is mediated by means of the sciatic, peroneal, and tibial nerves and the hindlimb flexor muscles.

Spinal cord and peripheral nerve lesions may be localized further by testing the integrity of the sensory innervation of the skin of the limbs. Areas of decreased or absent cutaneous sensation reflect lesions of the peripheral nerves innervating those regions of the skin or of the spinal cord segments in which those sensory nerves terminate. The skin over the trunk and much of the limbs is innervated by more than one peripheral nerve. Some areas of the limbs derive sensory innervation from a single peripheral nerve. These areas are termed the *autonomous zones* for those peripheral nerves. Damage to a peripheral nerve innervating the skin of a limb therefore will result in decreased to absent cutaneous sensation in the autonomous zone for that nerve. This information can be used to localize lesions. Decrease or loss of sensation to an entire limb or to limbs on both sides of the body suggest a lesion affecting several local spinal cord segments, or a transverse spinal cord lesion rostral to the affected limbs.

8.3.9 Other Spinal Reflexes

8.3.9.1 PERINEAL REFLEX

The perineal reflex is elicited by pinching the mucocutaneous junction of the anus. The normal reflex includes tightening of the sphincter muscle and contraction of the ventral tail muscles. Conscious sensation of the stimulus produces avoidance or protective responses that may range from a slight movement of the rear limbs and pelvis to a violent kick. The reflex is mediated by the internal pudendal nerve and spinal cord segments S1 to S5. Lesions in the nerve or in the sacral spinal cord result in a dilated, atonic rectal sphincter that fails to respond to noxious stimuli, as well as fecal impaction in the rectum and a dilated urinary bladder. The bladder is full of urine and dribbles whenever digital pressure is applied through the rectum or vagina. The perineum remains wet and may become irritated (“scalded”) by the continuous overflow of urine.

8.3.9.2

PANNICULUS (CUTANEOUS TRUNCI) REFLEX

The panniculus reflex is a wrinkling or flinching of the skin over the trunk when it is stimulated by light touch or by pinching. The skin over the caudal flank usually is the most sensitive. Run the tip of a closed hemostat over the skin, tap the skin lightly with the hemostat tip, or pinch the skin lightly with the hemostat. The normal response is a skin twitch, together with a conscious avoidance maneuver, such as moving away from the stimulus. The afferent part of the panniculus reflex is mediated through the dorsal nerve rootlets and the segmental spinal nerves that are distributed to the stimulated area. These ascend in the dorsal funiculi of the spinal cord and synapse on the efferent neurons in spinal segments C8 to T1 in ruminants and C8 to T2 in horses. The axons exit the ventral rootlet and form the thoracodorsal nerve, which innervates the cutaneous trunci muscle. The degree of reflex responsiveness varies among the large animal species. Sheep, goats, and many cattle possess a poor panniculus reflex. Horses and Zebu cattle have a well-developed reflex.

128

129

8.3.9.3

CERVICAL REFLEXES

Two reflexes have been described in the cervical area of the horse.[48] The cervical reflex is similar to the panniculus reflex. Tapping or pinching the skin of the caudal half of the cervical region results in a local skin twitch. The pathway is believed to involve the cervical segmental spinal nerves and the local spinal cord segments.

The cervicoauricular reflex is elicited in horses by covering the eye and lightly tapping the skin over vertebrae C1 to C3. As the skin is stimulated in normal horses, the ear reflexively twitches cranially and ventrally, and twitching of the facial musculature at the commissure of the lips is observed. This test measures the integrity of the dorsal funiculi of C1 to C3 spinal cord segments and the facial nerve in the medulla oblongata. The diagnostic usefulness of the test in ruminants is unknown.

Both these reflexes are variable and are not always found in normal animals. Increased experience of the examiner, however, seems to be associated with increased reliability of these reflexes. Both reflexes may be abnormal in animals with lesions affecting the cervical spinal cord, such as equine wobbler syndrome. The cervicoauricular reflex also may be decreased or absent in animals with caudal brainstem lesions involving the facial nerve or with peripheral facial nerve lesions.

8.3.9.4

“SLAP” TEST (LARYNGEAL ADDUCTOR REFLEX)

A sharp slap applied in the saddle region on one side of a horse's thorax results in adduction of the vocal folds of the larynx on the opposite side.[49] This reflex can be palpated as a contraction of the cricoarytenoideus lateralis muscle. Standing on one side of the animal the examiner curls his or her fingers around the dorsolateral aspect of the larynx on the opposite side. A slap is applied to the saddle region on the side on which the examiner is standing. The response is palpated as a small movement under the fingertips of the cricoarytenoideus lateralis muscle on the opposite side of the larynx. It is often useful to have a helper apply the slap rather than to have the examiner do so. The pathway for the reflex is only partially understood. Sensory information from the skin is relayed to the spinal cord in the segmental spinal nerves. The ascending information then crosses the spinal cord and runs rostrally in a contralateral pathway to the origin of the vagus nerve in the nucleus ambiguus in the medulla oblongata. Descending output from the nucleus ambiguus runs in the cervical vagosympathetic trunk and thence to the recurrent laryngeal nerve, which branches from the vagus in the cranial thorax. The recurrent laryngeal nerve runs rostrally alongside the trachea to the larynx.

Thus the pathway for this reflex is almost entirely contralateral to the side on which the stimulus (the slap) is applied. Abnormalities in the laryngeal adductor response are seen in animals that have lesions of the cervical spinal cord but also in those with caudal brainstem lesions, vagus nerve lesions, and lesions of the recurrent laryngeal nerve ("roarers"). The test's accuracy may be limited. In one study there was poor correlation when predicting the presence or absence of cervical spinal cord or brainstem disease.[50] Interpretation of the results depends on the experience of the examiner. It should also be interpreted considering the complete neurologic examination findings. Presence of the response bilaterally is normal. Unilateral absence of the response suggests a lesion in one of the structures described previously. Bilateral absence of the response is harder to interpret because it may be the result of a bilateral lesion or the inability to palpate the cricoarytenoid contraction in a large or heavily muscled horse. The laryngeal adduction elicited in this test also can be observed endoscopically. The laryngeal adductor response tends to fatigue, so it may disappear if tested repeatedly over a short period.

8.3.10 Muscle Mass and Tone

Normal mass and tone of the musculature depends on an intact nerve supply. Primary diseases of muscle and loss of use of a limb secondary to orthopedic disease are often associated with mild to moderate muscle atrophy that develops over weeks to months. Atrophy caused by denervation, however, is more severe and rapid in onset. Visible loss of mass of specific muscles or groups of muscles is most likely caused by damage to the nerve supply to those muscles, either by direct injury to peripheral nerves or injury to the origins of those nerves in the ventral horn gray matter of the spinal cord (Fig. 8-7). Knowledge of the central origins of the nerves to the limbs and the course of those nerves in the periphery can be used to specifically localize neurologic lesions (see Tables 8-4 and 8-5). Electromyography and nerve conduction testing can further be used to help identify muscle denervation and peripheral neuropathies (see Chapter 35). Regeneration of peripheral nerves after an acute insult can occur. Regeneration is accomplished by outgrowths of axonal buds from the proximal stump. The buds either grow along previous peripheral nerve rootlets or generate new neural pathways in concert with proliferation of myelin precursor cells. The rate of growth of the axonal buds has been estimated to be approximately 1 to 4 mm/day.[51]

Muscle tone can be evaluated in the recumbent animal by passively flexing the limbs. Evaluation is not accurate in the standing animal or in animals supported in slings because of resistance from taut bands of connective tissue. In normal animals repeated flexion is accompanied by an increase in the tone in the flexed limb. The limbs of animals with a lower motor neuron deficit remain flaccid. Small ruminants tend to show a greater relative amount of extensor tone in the limbs than do cattle or horses. Evaluation of the test must be conservative because some severely obtunded large animals display generalized hypotonia, even though the lower motor neurons are functional. The cause of the hypotonia is unknown.

129
130

Fig. 8-7 Muscle atrophy in the gluteal muscles in a horse with equine protozoal myeloencephalitis.

The tone of the forelimbs is controlled through spinal cord segments C6 to T1 and the radial, musculocutaneous, median, ulnar, axillary, and long thoracic nerves. The motor tone of the rear limbs is controlled through spinal cord segments L3 to S2 and the femoral, cranial and caudal gluteal, and sciatic nerves. The lower motor neurons to the anus originate in spinal cord segments S1 to S5, via the pudendal nerve. The tail is innervated by the coccygeal segmental spinal nerves.

8.3.11 Examination of Cranial Nerves

Examination of the cranial nerves is most easily carried out by examining the functions of groups of nerves that innervate particular regions of the head rather than performing the examination in a strictly numeric order. For example, examination of vision and other ocular functions such as the menace response, pupillary light reflexes, and physiologic nystagmus reveals the integrity of several cranial nerves, not only II, III, IV, and VI, but also V (sensory to the cornea), VII (motor to the eyelids), and VIII (providing vestibular input to control the functions of III, IV, and VI), as well as centers within the brain.

8.3.11.1 CRANIAL NERVE I—OLFACTORY NERVE

Reliable and specific testing of the sense of smell is difficult in animals. Large animals require an intact sense of smell to eat properly, so it can be inferred that animals with good appetites possess an adequate sense of smell. Having an animal track food moved from side to side in front of the nose may be helpful. Ensure that the food has an appealing odor. Irritating substances such as ammonia should not be used for evaluation of olfactory nerve function; such compounds stimulate nociceptors in the nasal mucosa, which are the dendrites of the maxillary nerve (cranial nerve V), rather than stimulating olfactory receptors innervated by the olfactory nerve. Loss of the sense of smell is more likely to be caused by disease within the nasal passages than by a primary neurologic disease.

8.3.11.2 CRANIAL NERVE II—OPTIC NERVE

Vision is the function of cranial nerve II, the optic nerve. Observing the animal's response to its environment provides a good initial assessment. Does it respond to visual cues, such as movement, or does it walk into objects? Noise may cause the animal to turn its head toward the sound, so the observer must be careful to distinguish such responses from those made in response to visual cues. A maze can be set up using straw bales or other objects, and the animal gently driven through the maze. Normal animals will avoid colliding with objects. Animals that are severely obtunded, however, may walk into objects even when they can see. Thorough evaluation of the complete neurologic examination is necessary to distinguish this from true blindness.

The menace response measures the integrity of the entire visual pathway. The ascending pathway runs from the retina via the optic nerves, midbrain, and internal capsule to the visual areas in the occipital lobe of the cerebrum. Information from the visual cortex is processed and relayed to the motor cortex. The descending pathway of the menace response runs from the motor cortex via the pons to the nucleus of the facial nerve in the medulla oblongata and thence via the facial nerve to the orbicularis oculi muscle. Input to this motor pathway also arises from the cerebellum. The menace test is performed by rapidly advancing the hand toward the eye and observing a reflex closure of the eyelids. In addition to the closure of the eyelids, some animals display a generalized avoidance response characterized by coordinated movement of the head and neck away from the stimulus. The opposite eye may be covered to ensure that only one eye is being stimulated. Care must

be taken not to touch the face or eyelashes. Many authors warn that air currents generated by rapid movement of the hand toward the face can elicit the response even in blind animals, but this has not been our experience. The menacing gesture is directed first at the nasal and then at the temporal parts of the visual field. Blindness in one visual field is termed *hemianopsia*. The menace response measures the integrity of the retina, optic nerve, optic chiasm, midbrain, internal capsule, and occipital cortex. There is approximately 90% crossing over of optic nerve fibers in the optic chiasm of livestock. Animals with a postchiasmal lesion in the internal capsule, midbrain, or occipital lobe will show hemianopsia in the contralateral visual field. In practical terms, lesions central to the optic chiasm cause loss of vision in the opposite eye, with apparently normal vision in the ipsilateral eye.

Menace deficit may be the result of facial nerve paralysis. In such cases the animal does not blink but shows avoidance of the stimulus by pulling the head away. Facial nerve deficits will be apparent in these animals by their inability to close the eyelids under any circumstances and by other signs such as facial drooping on the same side. Animals with cerebellar disease also may display a menace deficit, yet possess normal vision. The precise pathway by which the cerebellum influences the menace reflex is not known, but interruption of this pathway is thought to disrupt upper motor neuron control of the facial nerve, which becomes dysfunctional. Menace deficits resulting from facial nerve or cerebellar disease may be differentiated from deficits in other areas by maze testing. Animals with cerebellar or facial nerve disease retain visual acuity and maneuver through the course successfully. The maze test measures the patient's ability to identify and avoid obstacles. In addition to the optic pathways, the test measures the integrative pathways in the frontal and parietal lobes of the brain, the motor neurons, and the proprioceptive pathways (Table 8-6). Myasthenic diseases (e.g., botulism, hypocalcemia, or hypomagnesemia) result in bilaterally decreased menace and palpebral responses but do not produce blindness.

The pupillary light reflex measures the integrity of the retina, optic nerves, optic chiasm, pretectal and oculomotor nuclei in the midbrain, oculomotor nerve, ciliary ganglia, and constrictor pupillae muscle. The test is performed by shining a bright light into each eye and observing constriction of the pupil in the ipsilateral eye (direct response) and the contralateral eye (indirect response). Reducing the ambient light level may facilitate this test by causing the pupils to dilate. The reflex in large animals is considerably slower than observed in cats and dogs. A “swinging light” test has been recommended in large animals to reduce the blink and startle responses elicited by suddenly shining a bright light into the eyes.[47] A strong light source is slowly shone from one eye to the other while bringing it closer and closer to the head and observing the responses in each pupil. The effects on the pupillary light reflex of lesions at various levels along the visual pathway are shown in Table 8-6.

Unilateral lesions of the cerebral cortex result in blindness of the opposite eye. The pupillary light reflexes usually are normal. If the cortical disease is accompanied by increased intracranial pressure, the oculomotor nerve or nucleus may become dysfunctional because of midbrain compression, resulting in ipsilateral mydriasis.

Table 8-6 Guide to Neuroophthalmologic Lesion Location

	Menace Response		Pupillary Light Response		
Lesion Location	**Ipsilateral**	**Bilateral**	**Ipsilateral**	**Bilateral**	**Maze Test**
Unilateral retina, optic nerve	Absent	Present	Normal	Normal	Abnormal
Bilateral retina, optic nerve, optic chiasm	Absent	Absent	Fixed	Fixed	Abnormal
Unilateral oculomotor nerve	Absent	Present	Dilated nonresponsive	Normal	Normal
Unilateral occipital cortex	Present	Absent	Normal*	Normal*	Abnormal
Bilateral occipital cortex	Absent	Absent	Normal	Normal	Abnormal
Bilateral vagosympathetic trunk	Present	Present	Miotic	Normal	Normal
Bilateral cerebellar cortex	Absent	Absent	Normal	Normal	Normal†

* Assuming that no cortical swelling has occurred.

† Animals walk abnormally but recognize and generally avoid obstacles.

8.3.11.3

CRANIAL NERVES III, IV, AND VI—OCULOMOTOR, TROCHLEAR, AND ABDUCENT NERVES

The position of the globe in the orbit is governed by the activity of the oculomotor, trochlear, and abducent nerves. Dysfunctions of these nerves result in deviation of the globe that is constant in all head positions. Loss of oculomotor nerve function results in a ventrolateral strabismus. Trochlear nerve dysfunction results in rotation of the dorsal aspect of the globe away from the midline (dorsomedial strabismus). In large animals that have horizontal pupils, trochlear nerve lesions cause deviation of the pupil such that the medial aspect of the pupil is dorsal to the lateral aspect. The trochlear nerve crosses the midline twice in the area of the midbrain before exiting the cranial vault. Therefore unilateral lesions could result in contralateral or ipsilateral strabismus, depending on the location of the lesion within the brainstem. Lesions of the trochlear nerve are, in our experience, extremely rare. Loss of abducent nerve function results in medial strabismus with inability to retract the globe, which is best demonstrated by restraining the head of the patient, opening the palpebral fissure, and touching the cornea. The normal reflex is a retraction of the globe with protrusion of the third eyelid.

Function of the oculomotor, trochlear, and abducent nerves also is observed when testing the oculocephalic reflexes. When the head is turned from side to side a horizontal nystagmus is observed, with the fast phase of the nystagmus in the direction of the head movement. The sensory receptors for this reflex lie within the semicircular canals of the inner ear, and they detect angular acceleration of the head. Input from the

semicircular canals is transferred to the vestibular centers in the medulla oblongata and the cerebellum, and thence via the medial longitudinal fasciculus and reticular formation to the nuclei of cranial nerves III, IV, and VI. Lesions of the peripheral or central components of the vestibular system also can result in abnormal eye position (strabismus) and movement (nystagmus), described in more detail later. In such cases, however, the strabismus typically changes when the head and neck are moved, in contrast to the constant deviation of the globe seen with direct lesions to the oculomotor, trochlear, and abducent nerves. Vestibular dysfunction also results in spontaneous nystagmus, which can be used to differentiate these conditions from dysfunctions of nerves III, IV, and VI.

The oculomotor nerve is the motor nerve to the levator palpebrae superioris muscle, the most important of the muscles responsible for elevation of the upper eyelid. Lesions of the nerve cause ptosis (drooping of the upper eyelid) in addition to the signs described previously. Ptosis also can be induced by lesions of the sympathetic nerve supply to the eye because of paralysis of the superior tarsal muscle and in the horse, only, by lesions of the facial nerve, which innervates the levator anguli oculi medialis muscle (see later).[52]

8.3.11.4

CRANIAL NERVE V—TRIGEMINAL NERVE

The trigeminal nerve is sensory to the face and motor to the muscles of mastication. The sensory functions of the trigeminal nerve are tested by lightly stimulating the face using the tip of a closed hemostat. In animals that are head-shy, the examiner can use his or her fingers to stimulate the skin of the face. The forehead is innervated by the ophthalmic branch of the nerve, the upper jaw and muzzle by the maxillary branch, and the lower jaw by the mandibular branch. Each area should be tested specifically. The normal response is one of avoidance using neck, facial, and appendicular musculature; the animal usually pulls the head away and blinks simultaneously. Some areas such as the cheeks, forehead, and chin are normally less sensitive, whereas the periorbital region, the nasal planum, and the lips are very sensitive. The test evaluates the function of the sensory part of the trigeminal nerve, the trigeminal ganglion, the nucleus and spinal tract of the trigeminal nerve, the pontine sensory tract nucleus of cranial nerve V, the thalamus, the sensorimotor cortex, and the motor neurons of the head, which innervate the muscles of facial expression and run in the facial nerve (cranial nerve VII). After the trigeminal nerve enters the lateral aspect of the medulla, axons both ascend and descend through the medulla as the spinal tract of the trigeminal nerve. Ascending information ultimately reaches the sensorimotor cortex, where it is consciously perceived. Descending information projects to the nucleus of the facial nerve in the medulla and also into the first cervical spinal segment. Unilateral loss of facial sensation most commonly results from damage to the peripheral portion of the trigeminal nerve, the trigeminal ganglion in the petrosal bone of the skull, or the contralateral cerebral cortex. Lesions affecting the spinal tract of the trigeminal nerve in the medulla and midbrain would likely be fatal, because they also would affect adjacent respiratory and cardiovascular centers in the brainstem. Patients with bilateral facial hypoesthesia probably have bilateral cerebral cortex disease.

The palpebral reflex is elicited by lightly touching the periorbital area and observing a brisk closure of the eyelids. This reflex reflects the sensory function of the trigeminal nerve and the motor function of the facial nerve and orbicularis oculi muscle. Simultaneous loss of the menace response and the palpebral reflex suggests a lesion in the facial nerve or the orbicularis oculi muscle. Loss of the palpebral reflex with normal menace responses suggests a lesion in the trigeminal nerve or ganglion. Loss of menace response with preservation of the palpebral reflex indicates occipital cerebrocortical dysfunction (cortical blindness) or a cerebellar lesion.

131

132

The jaw should be opened to assess the strength of the masticatory muscles. This measures both the sensory (proprioceptive) fibers of the trigeminal nerve and the motor component of the nerve. Bilateral lesions of the

motor component of the trigeminal nerve result in a dropped jaw. Affected animals may protrude the tongue but can retract it normally when stimulated. Animals with dropped jaws may drool saliva because they cannot trap it within the oral cavity. Unilateral lesions of the trigeminal nerve produce asymmetric jaw closure, with a slight gap between the occlusal surfaces of the teeth on the affected side; these signs, however, are not readily apparent.

8.3.11.5

CRANIAL NERVE VII—FACIAL NERVE

The motor nucleus of cranial nerve VII originates in the middle and ventral part of the medulla oblongata. The motor fibers are distributed to muscles of facial expression. Just as the motor fibers are exiting from the lateral aspect of the brainstem they merge with axons from the parasympathetic facial nucleus. These fibers innervate the lacrimal and salivary glands. They separate from the motor component of the facial nerve as it traverses the petrous temporal bone. Lesions of CN VII located between the brainstem and the petrous temporal bone usually result in “dry eye.” More distal lesions, however, have no effect on tear production. The tone of the facial musculature is examined by palpation of the ears, lips, eyelids, and muzzle. Clinical signs of facial nerve dysfunction include drooped ear and lips, drooling saliva, and retention of food in the cheek pouch on the denervated side (Fig. 8-8). Closure of the eyelids is weak in partial facial nerve lesions and absent in severe lesions. Despite this, there is slight drooping of the upper eyelid (ptosis) because of paralysis of the frontalis muscle, which contributes to eyelid retraction. In species with a soft muzzle (e.g., horses, sheep, and goats), there is a marked deviation of the filtrum away from the side with the lesion after unilateral loss of facial nerve function. The filtrum of affected cattle is not deviated because of the large amount of fibrous tissue in the planum nasale. In chronic facial paralysis the face may be deviated toward the affected side because of atrophy and contracture of the denervated musculature of the face.

8.3.11.6

CRANIAL NERVE VIII—VESTIBULOCOCHLEAR NERVE

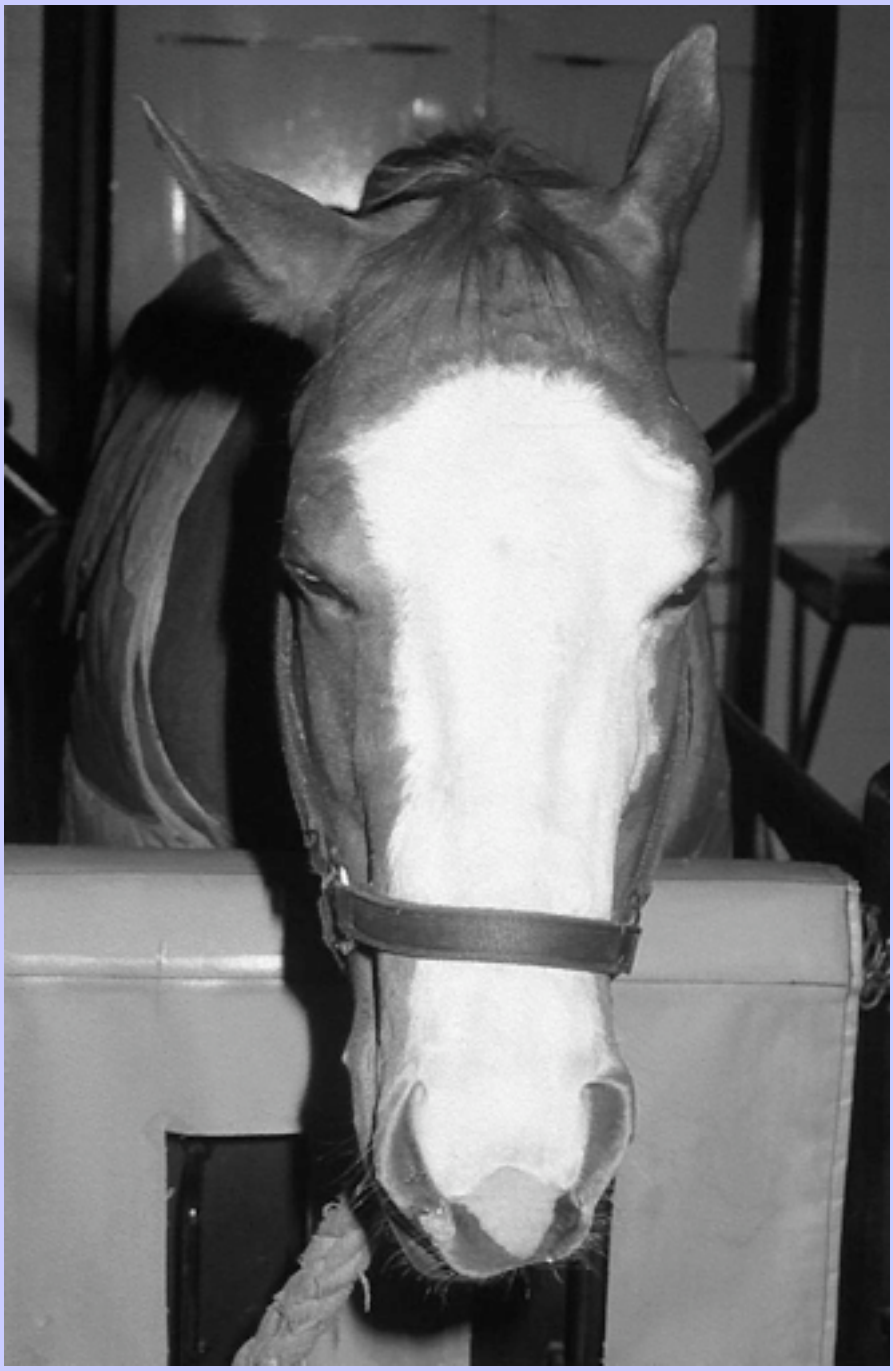
8.3.11.6.1

Vestibular System

The function of the vestibular system, which is composed of the sensory structures in the inner ear (semicircular canals, utriculus, saccule), the vestibular portion of cranial nerve VIII, and the central components of the vestibular system in the medulla oblongata and cerebellum, is tested by assessment of gait, extensor tone, head posture, and eye movements. Signs of vestibular dysfunction include a staggering gait, circling, falling, rolling, head tilt, and spontaneous nystagmus. Signs can be classified as peripheral, central, or paradoxic in type. Lesions affecting the inner ear or cranial nerve VIII result in signs of peripheral vestibular disease. Lesions affecting vestibular structures in the medulla oblongata result in central vestibular signs, and lesions affecting vestibular structures in the cerebellum result in paradoxic vestibular signs. Blindfolding affected patients results in a worsening of clinical signs because of elimination of compensatory mechanisms from optic centers. Recumbent animals with vestibular lesions tend to lie with the side of the vestibular lesion downward. When turned, these animals spontaneously rotate back to the lesion-down position and may strongly resist attempts to turn them over. Animals with unilateral vestibular disorders may have a ventral strabismus in the ipsilateral eye and a dorsal strabismus in the contralateral eye. This sign is seen with either central or peripheral vestibular lesions. Assessment of strabismus should be performed on the standing animal with the head held in normal posture. All species of livestock keep the eyes centered in the orbit when the head is in the neutral position. Cattle and sheep keep the optic plane parallel to the ground when the head is moved. This results in a positional ventrolateral strabismus of the right eye when the head is rotated to the left, and vice versa, and a ventral strabismus

when the head is raised. In contrast, the normal horse and goat maintain the eye in the center of the palpebral fissure in all head positions.

Fig. 8-8 Acute right facial paralysis in a horse with guttural pouch mycosis. Note the drooped right ear and deviation of the muzzle toward the left side.



Bilateral, symmetric lesions of the vestibular system are rare. They do not cause head tilt, nystagmus, or strabismus. Affected animals are reluctant to move. They stand with a base-wide posture, with the head held low, and fall easily when forced to move.

8.3.11.7

CRANIAL NERVES IX, X, AND XI—GLOSSOPHARYNGEAL, VAGUS, AND SPINAL ACCESSORY NERVES

Cranial nerves IX, X, and XI originate in the nucleus ambiguus, a column of motor neurons that extends from the middle to the caudal medulla oblongata, located in a ventrolateral position. They are motor to the muscles of the neck, pharynx, and palate. The vagus nerve contains efferent fibers that stimulate the secretions of glands of the visceral and respiratory mucosa and control forestomach motility in ruminants. The glossopharyngeal and accessory nerves carry afferent fibers from the mucosa of the tongue, larynx, and pharynx. The signs of glossopharyngeal and vagus nerve dysfunction include dysphonia (roaring, snoring), 132
dysphagia, and regurgitation. Animals with pharyngeal paralysis regurgitate food from the nose. Roaring is a 133
characteristic stertorous sound emanating from the larynx. The abnormal sound can be increased by exercise. Functional examination of these nerves should include auscultation of the larynx for stertorous airway sounds, observation of the animal as it swallows, passage of a nasogastric tube to evaluate deglutition, endoscopic examination to evaluate pharyngeal and laryngeal activity, and palpation of the cricoarytenoideus dorsalis muscle for atrophy. The slap test, described earlier, is a test for function of the vagal innervation of the larynx. Specific descriptions of the endoscopic appearance of pharyngeal paralysis and roaring are presented elsewhere (see Chapter 31).

Signs of spinal accessory nerve dysfunction are extremely rare and include atrophy of the trapezius, sternocephalicus, and brachiocephalicus muscles.

8.3.11.8

SYMPATHETIC INNERVATION OF THE HEAD—HORNER'S SYNDROME

Preganglionic sympathetic fibers that innervate structures of the head originate from the first three thoracic spinal cord segments. These fibers emerge with the origins of the nerves that form the brachial plexus. They ascend the neck in the peripheral vagosympathetic trunk to the cranial cervical ganglion under the tympanic bulla, where they synapse with postganglionic sympathetic fibers. The postganglionic fibers are distributed to the smooth muscles of the head through the ciliary nerves, passing through the petrous temporal bone area. Lesions anywhere along the course of the preganglionic or postganglionic sympathetic nerves, in spinal cord segments T1 to T3 or, very rarely, in the upper motor neuron component of the sympathetic pathway in the cervical spinal cord or brainstem (tectotegmentospinal tract) cause a characteristic constellation of clinical signs known as *Horner's syndrome*. Signs include miosis, enophthalmos, ptosis, and increased warmth on the ipsilateral side of the face. In cattle there is a loss of sweating on the ipsilateral side of the planum nasale, whereas in horses there is excessive sweating on the affected side. The enophthalmos is caused by paralysis of the periorbital smooth muscle that normally pushes the globe toward the surface of the orbit. The relaxation of the periorbita results in the sinking of the globe. Miosis is produced by the lack of pupillary dilation in response to normal sympathetic activity.

Diseases that could produce Horner's syndrome in large animals include compressive lesions of the gray matter in the T1 to T3 spinal segments, neoplasms (lymphosarcoma, melanoma, or neurofibroma), mediastinal or thoracic abscesses, abscesses in the cervical sympathetic trunk, esophageal perforations, guttural pouch mycosis, otitis media and interna, and retrobulbar abscesses. Transient Horner's syndrome may occur after

intravenous injection of xylazine. Preganglionic and postganglionic denervation may be differentiated by instillation of 1:1000 epinephrine (0.1 mL) into the eye with the miotic pupil. Pupillary dilation occurs by 20 to 40 minutes in eyes with postganglionic and preganglionic lesions, respectively. This test is unreliable in horses, however, and therefore is not useful in this species. Lesions of the mesencephalon (brainstem) at the level of the rostral colliculus may produce miotic pupils without other signs of Horner's syndrome. This is a common sign in cattle with polioencephalomalacia and lead poisoning.

8.3.11.9 CRANIAL NERVE XII—HYPOGLOSSAL NERVE

The hypoglossal nerve supplies motor impulses to the muscles of the tongue and the geniohyoideus muscle. The cell body of the nerve is located in the dorsomedial aspect of the caudal medulla oblongata. Hypoglossal nerve function is tested by pulling the tongue out of the mouth. Normal animals should have forceful resistance to passive manipulation of the tongue. Lesions of the hypoglossal nerve result in flaccidity of the tongue. With unilateral lesions, the tongue falls out of the mouth away from the side with the lesion. Chronic lesions of the hypoglossal nerve result in deviation of the tongue toward the side of the lesion because of muscle atrophy and contracture on the affected side.

8.3.12 OTHER ASPECTS OF PHYSICAL EXAMINATION OF THE PATIENT WITH NEUROLOGIC DISEASE

Diagnosis of a neurologic disease can often be facilitated by the observation of physical abnormalities in other systems. When one examines animals with chronic ataxia or tetraparesis, the head, neck, and back should be gently manipulated while the spine is palpated for crepitation or swelling. This finding could indicate the presence of a fracture, malformation, or luxation of one or more cervical vertebrae or vertebral osteomyelitis. Do not manipulate the neck whenever there is evidence of acute cervical vertebral trauma. Swelling, bruising, or hair loss on the skin around the head or bleeding from the ears or nose could signify cranial trauma. Hair loss and dermatitis around the perineum and medial thigh may indicate urinary incontinence. In neonates a hairless patch over the dorsum of the spine could indicate a meningomyelocele. Displacement of the sacrum could indicate sacroiliac luxation. Crepitation over coxofemoral or stifle joints of recumbent cattle could indicate a luxation or fracture. If luxation of the coxofemoral joint is suspected, the animal should be rolled on its back, and the length of the two pelvic limbs should be compared while the legs are held in extension. A pelvic examination should be performed in all large animals to detect displacement of the hip joint into the obturator foramen or fractures through the shaft of the ilium. All joints should be passively manipulated to detect dislocations or fractures. The heart should be auscultated for murmurs that could suggest left-sided endocarditis because such lesions can shower bacteria into the meninges. Odors on the breath such as ammonia, ketones, or petroleum distillates could provide clues about possible toxic causes. Identification of concurrent bronchopneumonia may indicate the possibility of thromboembolic meningoencephalitis in cattle or herpesvirus myelitis in horses. The ocular fundus should be examined ophthalmoscopically to detect retinal hemorrhages (trauma), papilledema (increased intracranial pressure), or vasculitis.

8.3.13 Examination of the Neonate

Most of the physical diagnostic techniques described in the preceding paragraph for the adult may be applied in examination of the neonate. Most spinal reflexes of livestock are well developed after birth. In the normal foal under 3 weeks of age, the limbs are hypertonic and hyperreflexic, with occasional myoclonus occurring after percussion of the patellar or triceps tendons. This hyperreflexia is most pronounced in the rear limbs. A lack of

menace response for up to 2 weeks after delivery also has been observed. Nevertheless, foals are visual and aware of their surroundings almost immediately after birth. When restrained the newborn foal relaxes into a trancelike state, periodically awakening and struggling violently before becoming passive again.

The results of daily examinations of 10 normal calves indicated that the spinal reflexes were present by 24 hours after birth. Most cortical responses were developed by 3 weeks of age. Bottle-reared calves aggressively attempt to suck while being examined, including vigorously butting of the handler with the head. Beef calves attempt to escape restraint and do not attempt to suck. See Chapters 15 and 21 for more details on neonates.

133

134

8.4 LOCALIZATION OF CENTRAL NERVOUS SYSTEM LESIONS

Localization of a CNS lesion on the basis of clinical signs is vital because many specific diseases are restricted to particular regions of the CNS. Thus localization of a CNS lesion facilitates both differential diagnosis and specific diagnosis of the disorder. Ancillary diagnostic testing is determined both by the likely differential diagnoses and by the location of the lesion within the nervous system. Once the clinician has located the anatomic site of a neurologic lesion, a list of rule-out diagnoses may be formulated. Additional tests, including CSF analysis, radiography, magnetic resonance imaging (MRI), computed tomography (CT), serology, electroencephalography, brainstem auditory evoked response (BAER), and myelography, can be performed to further characterize the disease.

Lesions can be localized to one of seven regions of the CNS: cerebral cortex and thalamus, midbrain, cerebellum, medulla oblongata, spinal cord, peripheral nerve (either cranial nerves or spinal nerves), and muscle. Further localization to specific areas of these larger structures often can be determined after the neurologic examination.

8.5 LOCALIZATION OF NEUROLOGIC DISEASES BY MAJOR CLINICAL SIGNS

8.5.1 ABNORMAL MENTATION AND BEHAVIOR AND SEIZURES

Decreased mental alertness (dullness, obtundation, stupor, coma) is the most common change of mental status in animals with neurologic disease, although increased responsiveness to external stimuli (anxiety, mania, aggression) sometimes occurs. Altered mentation results from changes in the cerebrum, thalamus, or ARAS. Diseases affecting the ARAS tend to produce severe changes in mentation (stupor, coma), whereas those affecting the cerebrum or thalamus tend to produce a wider range of clinical signs, from slight dullness to coma. In order of worsening severity, decreased mental status in animals can be categorized as follows.

8.5.1.1 DULL, MILD TO MODERATE OBTUNDATION

Animals have decreased responsiveness to their surroundings, may ignore visual and auditory stimuli, may stop interacting with herdmates, and may be inappetent.

8.5.1.2 SEVERE OBTUNDATION

Animals are ambulatory but sometimes appear to be blind and walk into objects. They will respond only to fairly strong stimuli such as very loud noises and vigorous handling.

8.5.1.3

STUPOR

Animals appear to be asleep and will respond only to very vigorous and painful stimuli. Responses even to these stimuli are blunted.

8.5.1.4

COMA

Animals appear to be asleep and will not respond even to the most painful stimuli. Animals in coma are recumbent. They may adopt abnormal posture, particularly decerebrate posturing (opisthotonos, all four limbs rigidly extended), and may have other abnormal signs such as loss of the oculocephalic and pupillary light reflexes.

8.5.1.5

MANIA, ANXIETY

Animals that exhibit abnormally heightened reactions and responses vary widely in the severity of their signs, from mildly overreactive to bellowing, rearing, and attacking people, animals, or objects around them.

8.5.1.6

SEIZURES, COLLAPSE

Episodic abnormalities of behavior or consciousness are usually the result of seizure activity, narcolepsy or cataplexy, or syncopal attacks caused by cardiovascular or respiratory dysfunction. Intermittent toxicities or fluctuating metabolic abnormalities, such as occasionally occur with hepatic encephalopathy, also may cause episodic changes in mentation and behavior. Animals with a history of episodic collapse should undergo a very thorough physical examination to determine whether disease of the cardiovascular system (e.g., cardiac arrhythmias, intermittent hemorrhage) or respiratory system (e.g., laryngeal paralysis) is present. Animals that have seizures usually have a period of abnormal behavior after the seizure (postictal phase of the seizure), whereas those with narcolepsy or cataplexy or nonneurologic causes of collapse usually do not. Seizures and narcolepsy/cataplexy are discussed in more detail later.

Signs of cerebral and thalamic disease are variable in severity and are difficult to distinguish from each other clinically. The thalamus and cerebrum can be thought of as a functional unit, to some extent, because the thalamus is the relay center via which sensory information from the periphery reaches the cerebrum and through which motor impulses from the cerebrum are transmitted to the brainstem motor centers. Diffuse cerebral disease often results from metabolic, toxic, or infectious diseases. Increased intracranial pressure, the consequence of early acquired hydrocephalus, mass lesions within the cranial vault, inflammatory diseases, or cerebral edema, tends to produce signs of diffuse cerebral disease, which can range from mild to severe. Mild to moderate cerebral dysfunction usually results in an animal with decreased mental awareness, or, more rarely, excitement and overreaction. Diffuse disease does not result in circling, and gait on a level surface may appear normal, or almost so. Gait is abnormal, however, when the animal is challenged to ascend or descend slopes, step over objects on the ground, step onto and off curbs, circle, or back up. Both ataxia and paresis become apparent, although the former usually is more obvious. Postural and proprioceptive reflexes and reactions similarly are abnormal. When an animal is walking at normal speed on a level surface, local reflexes in the spinal cord and regulatory information from the red and reticular nuclei in the brainstem control simple gait patterns. Movements that require visual input or complex limb and body integration of movements are initiated in motor centers of the cerebral cortex. The combination of normal gait on a level surface with

obvious proprioceptive and postural deficits should immediately alert the examiner to the likelihood of cerebral or thalamic disease.

Response to visual stimuli, such as an open hand directed toward the face, may be decreased or absent because of involvement of the visual pathways in the cerebral cortex or the internal capsule (see Blindness, later). Pupillary light reflexes and oculocephalic reflexes usually are normal in animals with cerebral disease, except in severe cases. Response to all sensory input to the cerebrum often is decreased, but this is most obvious in the head, where the facial reflex (twitching of the facial skin and superficial musculature in response to tactile stimuli) and the palpebral reflex are decreased to varying degrees. It is common to mistake this for the presence of a second lesion, affecting the trigeminal nerve, facial nerve, or both, but such lesions need not be present to account for these clinical signs. In trigeminal or facial nerve lesions the clinical deficits tend to be more severe than when cerebrocortical disease is present, and mental status is normal when the cranial nerve lesions are peripheral in location. Horses with severe cerebrocortical lesions may fail to retract the tongue after it is pulled from the mouth but can do so when stimulated vigorously. Animals with lesions of the hypoglossal nerve may not be able to retract the tongue at all, or the tongue may be very weak.

The hypothalamus regulates primitive functions such as eating, drinking, cardiovascular function, and sexual behavior. Lesions of the hypothalamus may cause behavioral changes ranging from profound depression, rage, and inappropriate sexual activities to unusual affection, as well as polydipsia, polyuria, bradycardia, and abnormal appetite (pica).

134

135

Seizures are the physical manifestations of spontaneous paroxysmal electrical activity in the brain. Although a focus of abnormal activity may originate in the thalamus or elsewhere in the brainstem, spread of this activity to the cerebral cortex results in the observable seizure activity. When the seizure activity is limited to a small area of the cerebral cortex the seizure that results is focal in type, resulting only in localized abnormal motor activity, such as muscular twitching in the face or in one limb, or episodes of abnormal behavior. More commonly the seizure is generalized, or starts focally and becomes generalized, to the entire cerebral cortex. Generalized seizures cause loss of consciousness, collapse, and generalized tonic-clonic motor activity. The presence of seizures necessitates a localization of the neurologic lesion to the cerebrum, but the initiating cause may lie elsewhere in the brain; the origin may even be extracranial. *Epilepsy* is a term that means repeated seizures of any cause, although it is often used to indicate seizures of unknown cause. The nature of the seizure, whether focal or generalized, is not a reliable indicator of the underlying cause. Congenital or idiopathic epilepsy, such as benign epilepsy of Arabian foals, usually causes generalized seizures. Partial or focal seizures more commonly indicate an acquired cause. Animals with seizures should undergo a complete physical examination, together with diagnostic testing for suspected toxins and underlying metabolic diseases, as well as a thorough neurologic examination to localize any interictal neurologic signs. Further diagnostics, such as CSF analysis and MRI, are performed as indicated after this initial workup.

When cerebral and thalamic disease is lateralized or asymmetric in severity, asymmetry of clinical signs becomes apparent. Circling occurs often, ranging from a tendency to drift toward one side to obvious and persistent circling. Circling caused by forebrain disease remains more a tendency to circle rather than compulsive circling, which occurs in midbrain disease. Even in more severe cases it usually is possible to stop the animal from circling, although it may be very reluctant to turn in the opposite direction. Proprioceptive and postural reaction deficits are present in the limbs on the side of the body opposite to the lesion (contralateral) and vary in severity with the severity of the underlying neurologic disease. A head turn toward the side of the lesion (ipsilateral) may be present, but head tilt is not found. The absence of signs such as head tilt, nystagmus, and strabismus, together with the presence of contralateral proprioceptive and postural reaction deficits, distinguishes forebrain lesions from those affecting the vestibular system. In the latter, head tilt,

nystagmus, and/or strabismus usually are present, and proprioceptive and postural reaction deficits either are absent (peripheral vestibular disease) or are present ipsilateral to the lesion (central vestibular disease, see later).

Specific diseases associated with the cerebrum of ruminants and horses are given in Tables 8-7 and 8-8, respectively.

Table 8-7 Diseases of Ruminants That May Produce Cortical or Thalamic Signs

Disease	Predominant Clinical Signs	Species Affected
Rabies	Obtundation, excitement, aggressiveness, hyperesthesia, analgesia, anesthesia, proprioceptive deficits, recumbency, propulsive walking, head pressing, tenesmus, hypersexuality, salivation	Cow, sheep, goat
Trauma, hematoma, brain edema	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, opisthotonos, facial anesthesia, weak tongue, convulsions, anisocoria (late), head tilt, head pressing, blood from ears or nose, decerebrate rigidity	Cow, sheep, goat
Polioencephalomalacia	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, facial anesthesia, weak tongue, anisocoria (late), head pressing, opisthotonos, convulsions, odontoprisis, decerebrate rigidity	Cow, sheep, goat
Sulfur poisoning	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, facial anesthesia, weak tongue, anisocoria (late), head pressing, opisthotonos, convulsions, odontoprisis, decerebrate rigidity	Cow, sheep, goat
Lead poisoning	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, facial anesthesia, weak tongue, anisocoria (late), head pressing, opisthotonos, odontoprisis, convulsions, decerebrate rigidity	Cow, sheep, goat
Salt poisoning	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, opisthotonos, facial anesthesia, weak tongue, convulsions, anisocoria (late), head tilt, head pressing, decerebrate rigidity	Cow, sheep, goat
Scrapie	Chewing, licking, wool break, depression, weight loss, ataxia, reduced menace, hypertonicity, hyperreflexia, proprioceptive deficit, recumbency, coma	Sheep, goat
Bovine spongiform encephalopathy	Aggression, weight loss, milk production, ataxia, proprioceptive deficit, recumbency, coma	Cow
Border disease	Ataxia, tremors, bunny-hopping	Sheep, goat
Vitamin A deficiency	Obtundation, somnolence, blindness with fixed pupils, ataxia, proprioceptive deficits, facial anesthesia, weak tongue, head pressing, opisthotonos, convulsions, odontoprisis, decerebrate rigidity	Cow, sheep, goat
Brain abscess, meningitis	Recumbency, opisthotonos, blindness, hyperesthesia, stiff neck, proprioceptive deficit, ataxia, head pressing, depression, coma	Cow, sheep, goat

	Plant poisonings	Convulsions, blindness, ataxia, propulsive walking, head pressing, odontoprisis, hyperexcitability, salivation, proprioceptive deficit, sudden death, vomiting, fetal malformations	Cow, sheep, goat	
	Nitrofurazone toxicosis	Hyperirritability, propulsive running, muscular tremors, blindness, convulsions	Cow	135
	Grass staggers	Tremor, ataxia that worsens with excitement or exercise	Cow, sheep, goat	136
	Pseudorabies	Obtundation, ataxia, hyperesthesia, paresthesia, aggressiveness, fear, head pressing, propulsive walking, hypersexuality, salivation, coma, convulsions, recumbency, conscious proprioceptive deficit	Cow, sheep, goat	
	Malignant catarrhal fever	Aggression, rage, proprioceptive deficit, depression, head pressing, blindness, nystagmus, bellowing, mucosal and skin erosions, lymphadenopathy, diarrhea	Cow	
	Caprine arthritis-encephalitis	Obtundation, ataxia, head pressing, convulsions, coma	Goat	
	Maedi-visna	Obtundation, ataxia, head pressing, convulsions, coma	Sheep	
	Sarcocystis species infection	Seizures, blindness, opisthotonos, nystagmus, ataxia, muscular weakness, tremors, hyperexcitability, hypersalivation, recumbency	Cow	
	Brain tumor	Obtundation, facial paresis or paralysis, facial anesthesia or analgesia, head tilt, strabismus, nystagmus, loss of menace, hypermetria, ataxia	Cow	
	Sporadic bovine encephalomyelitis	Blindness, circling, ataxia, proprioceptive deficits, pleural friction rubs, pericardial friction rubs, abdominal tenderness	Cow	
	Urea poisoning	Muscle tremor, bloat, salivation, incoordination, struggling, ataxia, proprioceptive deficit, recumbency, bellowing, coma, convulsion	Cow	
	Ammoniated feed toxicosis	Trembling, fear, uncontrolled running, crashing through objects, coma, convulsion	Cow	
	Diplodiosis	Blindness, ataxia, obtundation, recumbency, convulsions, hyperesthesia	Cow	
	Ceroid lipofuscinosis	Blindness, ataxia, weight loss, coma, convulsion	Cow	
	Hydrocephalus, hydranencephaly, microcephaly, anencephaly	Blindness, ataxia, proprioceptive deficit, ventrolateral strabismus, failure to suckle, dysphonia	Cow, sheep, goat	
	Citrullinemia	Recumbency, coma, convulsions, death by 4 days of age	Cow	

Globoid cell leukodystrophy	Ataxia, proprioceptive deficits, hyperreflexia, depression, coma	Sheep
Infectious bovine rhinotracheitis	Fever, bellowing, coma, convulsions, somnolence, hyperexcitability, hyperesthesia, proprioceptive deficit, recumbency	Cow
Insecticide poisoning (organophosphate carbamate)	Salivation, vaginal discharge, diarrhea, tremors, coma, convulsion, diarrhea, proprioceptive deficit, recumbency	Cow, sheep, goat
Organochlorine poisoning	Tremors, hyperesthesia, recumbency, coma, convulsions	Cow, sheep, goat
Propylene glycol poisoning	Depression, bloat, ataxia, recumbency, proprioceptive deficit	Cow, sheep, goat
Ethylene glycol poisoning	Obtundation, somnolence, blindness, ataxia, proprioceptive deficits, facial anesthesia, weak tongue, head pressing, opisthotonos, convulsions, odontoprisis, decerebrate rigidity	Cow, sheep, goat
Nitrofurazone poisoning	Obtundation, proprioceptive deficit, recumbency, convulsion, coma	Cow, sheep, goat
Hypocalcemia	Cow, doe: weakness, ataxia, inappetence, bloat, proprioceptive deficit, cool extremities, weak pulse, bizarre head posture, dysuria	Cow, goat
	Ewe: rigidity; tremors; hyperesthesia; convulsions; rapid, irregular breathing; odontoprisis	Sheep
Hypomagnesemia	Stiffness, hyperexcitability, recumbency, ataxia, proprioceptive deficit, muscle tremors	Cow
Nervous ketosis	Aggressiveness, tremors, ataxia, paresthesia, recumbency, proprioceptive deficit, hyperesthesia, bellowing	Cow
Hypoglycemia	Coma, semicoma, convulsions, blindness, hyperesthesia, cold extremities	Cow, sheep, goat
Nervous coccidiosis	Diarrhea, recumbency, obtundation, somnolence, blindness, proprioceptive deficit, propulsive walking, head pressing	Cow
Hepatic encephalopathy	Hyperexcitability, aggression, rage, odontoprisis, ataxia, proprioceptive deficit, head pressing, coma, convulsions, semicoma, blindness, tenesmus, rectal prolapse	Cow, sheep, goat
Idiopathic epilepsy	Intermittent psychomotor seizures	Cow, goat
Narcolepsy	Sleep state, recumbency, loss of consciousness, loss of motor activity, rapid eye movement	Cow
Propylene glycol toxicosis	Ataxia, obtundation, bloat, characteristic garlic-like odor	Cow, sheep, goat

	Coenuris cerebralis	Blindness, circling, ataxia, conscious proprioceptive deficit, head tilt, recumbency, coma, convulsions	Sheep
	Theileriosis (central nervous system form, exotic)	Depression, hypersensitivity, ataxia, circling, paralysis, convulsions	Cow
	Babesiosis (exotic)	Odontoprisis, ataxia, conscious proprioceptive deficits, coma, convulsions	Cow
	Louping ill (exotic)	Fever, anorexia, obtundation, constipation, muscular tremors, head tremors, hypermetria, ataxia, proprioceptive deficits, hyperexcitability, incoordination, rabbit hopping gait, recumbency, convulsions, coma	Sheep, cow
	Borna disease (exotic)	Head tremors, hyperesthesia, ataxia, anorexia, propulsive walking, coma, convulsions	Cow, sheep, goat
	Sarcocystis	Fever, weight loss, tremors, weakness, diarrhea, loss of hair on the tail switch, abortions	Cow
	Heartwater (exotic)	Hyperesthesia, behavioral changes, muscular fasciculations, hypermetria, ataxia, conscious proprioceptive deficits, head pressing	Cow, sheep, goat
	Trypanosomiasis (exotic)	Ataxia, conscious proprioceptive deficit, somnolence, circling, head pressing	Cow

136

137

Table 8-8 Diseases of the Horse That Produce Cortical Disease

Disease	Predominant Clinical Signs
Hepatoencephalopathy	Aggression, rage, hyperexcitability, odontoprisis, ataxia, proprioceptive deficit, head pressing, convulsions, obtundation, coma, semicoma, blindness, fear, red urine (hemolysis), icterus
Parasitic migration	Head tilt, hyperexcitability, odontoprisis, ataxia, proprioceptive deficit, head pressing, circling, coma, semicoma, blindness, anisocoria, convulsion, tongue dystonia
Rabies	Recumbency, ataxia, proprioceptive deficit, aggression, depression, coma, semicoma, head pressing, circling, propulsive walking, mydriasis, tenesmus, fear, continual chewing
Leukoencephalomalacia	Recumbency, ataxia, proprioceptive deficit, aggression, obtundation, coma, semicoma, head pressing, circling, propulsive walking, mydriasis, tenesmus, fear, continual chewing
Brain abscess, meningitis	Head pressing, blindness, conscious proprioceptive deficit, ataxia, circling, depression, convulsions, hyperexcitability, stiff neck, rigid legs, fever, propulsive walking
Brain tumor	Depression, facial paresis or paralysis, facial anesthesia or analgesia, head tilt, strabismus, nystagmus, loss of menace, hypermetria, ataxia
Trauma, hematoma	Head pressing, blindness, conscious proprioceptive deficit, ataxia, circling, depression, convulsions, hyperexcitability, stiff neck, rigid legs, fever, propulsive walking, blood from ear or nose
Viral encephalomyelitis Eastern equine encephalomyelitis Near Eastern encephalitis Venezuelan equine encephalomyelitis Western equine encephalomyelitis Equine herpesvirus 1	Head pressing, blindness, conscious proprioceptive deficit, ataxia, circling, depression, coma, convulsions, recumbency, hyperexcitability, stiff neck, rigid legs, fever, propulsive walking
West Nile virus	Fasciculations of neck and facial muscles in addition to the other signs
Borna	
Equine protozoal myeloencephalitis	Seizures, head tilt, facial paralysis, circling, nystagmus, dysphagia, facial paralysis, blindness, ataxia, paresis, hyporeflexia, hyperreflexia
Hydrocephalus	Coma, semicoma, blindness, somnolence, head pressing, dysphonia, ataxia, conscious proprioceptive deficit, weak tongue
Idiopathic epilepsy	Intermittent psychomotor seizures, normal interictal periods
Narcolepsy	Intermittent sleeplike states with stress, normal between attacks

Diseases that are restricted to the thalamus are rare in domestic animals. Most lesions affecting the thalamus alone result from infarctions or parasitic migration through the CNS. The thalamus may be involved in multifocal nervous system disease, such as occurs with infectious diseases. The clinical signs of thalamic disease are, for the most part, similar to signs of cerebral dysfunction.

8.5.2 Blindness and Ocular Abnormalities

Blindness may be the result of lesions in the eye, optic nerve, optic chiasm, or central projections of the visual pathways. Ophthalmic examination, including fundic examination, should be part of the routine physical examination. Animals presented with the complaint of blindness should receive a more detailed ophthalmic examination to determine whether primary ocular disease is the cause of the problem (see Chapter 39). Sophisticated diagnostics such as electroretinography (ERG) may be indicated in some animals. When no ocular disease can be found to account for blindness, a lesion in the nervous system is likely to be responsible. Observing the animal's ability to negotiate its environment, particularly in unfamiliar surroundings, and eliciting 137
the menace reflex are the primary methods of determining visual function. Further testing can be performed by 138
setting up a maze of objects for the animal to negotiate, by using different light levels and assessing vision in bright versus dim light, and by blindfolding each eye in turn when unilateral deficits are suspected. Blindfolding should be used judiciously, because of the stress caused to the patient and the risks of worsening clinical signs in animals that do have visual deficits or other deficits such as vestibular dysfunction. Eighty percent to 90% of optic nerve fibers (axons of retinal ganglion cells) cross to the opposite side of the brain in the optic chiasm of ungulates; thus central representation of vision in these species is predominantly contralateral. Fibers that remain uncrossed originate from the temporal aspect of the retina. Lesions in the visual apparatus distal to the optic chiasm (i.e., lesions of the globe, the retina, or the optic nerve) produce ipsilateral visual deficits. Lesions proximal to the optic chiasm produce lesions in the opposite visual field (contralateral hemianopsia). The following discussion refers to severe or complete lesions, because these are most easily understood and described. Partial lesions will produce similar but milder signs, for example, reduced visual acuity rather than complete blindness. Absent or reduced menace reflex also can be caused by lesions of the facial nerve (cranial nerve VII), the cerebellum, or the cerebrum. Animals with facial nerve lesions can see but cannot blink even when the canthi of the eye are touched. Animals with cerebellar disease can see and can blink in response to the examiner touching the periorbital area. Cerebellar disease causes additional signs such as intention tremor, hypermetria, and ataxia. Animals with moderate to severe cerebral disease usually will blink in response to tactile stimulation of the face and periorbital area but appear to have decreased vision and may have a reduced to absent menace reflex (see earlier). Localization of lesions causing blindness is summarized in Table 8-6.

Pupil size and movement of the globes are mediated via cranial nerves II, III, IV, and VI and the sympathetic innervation of the eye. Clinical signs of diseases affecting these nerves are described earlier in the sections on cranial nerves and Horner's syndrome.

8.5.3 Circling

Circling can be a manifestation of lateralized disease in several regions of the brain: the cerebrum and thalamus, the midbrain, or the medulla oblongata. Circling associated with cerebral disease is toward the side of the lesion (ipsiversive) and is thought to result from lesions affecting the deep structures of the cerebrum or thalamic components rather than the cerebral cortex. Animals that circle secondary to cerebral disease often have a head turn toward the side of the lesion in addition to the circling. Whereas gait may appear normal on a level surface, affected animals have proprioceptive and postural reaction deficits on the side of the body contralateral to the lesion. Head tilt and spontaneous nystagmus are not present. Physiologic nystagmus (the oculocephalic reflex) is

normal when the examiner turns the animal's head from side to side. The severity of circling seen with lateralized cerebral disease is variable, from a subtle tendency to marked circling.

Diseases affecting solely or predominantly one side of the midbrain also result in circling. The circling is ipsiversive, occurs without manifestations of head tilt or spontaneous nystagmus, and is accompanied by contralateral proprioceptive and postural reaction deficits. Circling in midbrain disease is compulsive, in contrast to that seen in cerebral disease or vestibular disease. In both cerebral and midbrain disease the animal's level of consciousness usually is decreased, more severely with midbrain than cerebral disease. Midbrain lesions also may cause abnormalities of the oculocephalic and pupillary light reflexes because of the involvement of the somatic and parasympathetic nuclei of the oculomotor nerve (cranial nerve III) and the medial longitudinal fasciculus. The medial longitudinal fasciculus relays sensory information from vestibular centers in the medulla oblongata to the nuclei of cranial nerves III, IV, and VI.

Severe midbrain disease results in decerebrate posture: the animal is unconscious and in opisthotonus (extreme extension of the head and neck) with extensor rigidity of all four limbs. Severe midbrain disease may be the result of traumatic injuries or infectious diseases and particularly is a consequence of increased intracranial pressure from a variety of causes. When intracranial pressure is increased above normal there is a tendency for the occipital lobes of the cerebrum to be herniated caudally, under the tentorium cerebelli. This results in compression of the midbrain and is usually fatal. The presence of decerebrate rigidity warrants a very grave prognosis and the need for immediate and aggressive treatment with agents that decrease intracranial pressure (intravenous mannitol, dimethyl sulfoxide [DMSO], and other diuretics).

8.5.4 Head Tilt and Nystagmus

The presence of a head tilt, wherein one ear is held closer to the ground than the other, indicates disease of the vestibular system. Head tilt usually is accompanied by spontaneous (abnormal) nystagmus and a variety of other clinical signs. Vestibular disease can be classified as peripheral or central. Peripheral vestibular disease occurs when lesions of the vestibular apparatus of the inner ear (utricle, saccule, semicircular canals) are present or when there is abnormality of the peripheral portion of the vestibulocochlear nerve (cranial nerve VIII). Animals with peripheral vestibular lesions have normal mentation but may be extremely disoriented, making assessment of mentation difficult. The head tilt in peripheral vestibular disease is toward the side of the lesion. The vestibular system is involved in the maintenance of normal posture. Unilateral peripheral vestibular dysfunction causes decreased extensor tone in the limbs ipsilateral to the lesion and increased extensor tone in the contralateral limbs, resulting in the clinical signs of leaning, falling, and rolling toward the affected side. Proprioception and postural reactions are normal in peripheral vestibular disease, although they may be hard to evaluate in severe cases and in larger animals. Peripheral vestibular lesions produce a horizontal or rotatory nystagmus, with the fast phase directed away from the side of the lesion. The direction of the nystagmus in relation to the rest of the head is unchanged no matter what the position of the head. Physiologic nystagmus may be absent in severe cases, but more often it is decreased, particularly when the head is turned toward the side of the lesion. The facial nerve runs in proximity to the petrous temporal bone, and facial paralysis may be present in animals with peripheral vestibular disease when the facial nerve also is damaged by the underlying cause, such as may occur in traumatic injuries or severe otitis media or interna. Similarly, involvement of the postganglionic sympathetic nerve to the eye as it courses through the petrous temporal bone results in an ipsilateral Horner's syndrome (ptosis, miosis, enophthalmos, facial sweating in horses, reduced sweating on the nasal planum in cattle).

Lesions within the vestibular centers in the medulla oblongata and cerebellum also cause vestibular dysfunction. Central vestibular disease may produce clinical signs similar to peripheral vestibular lesions but can be

distinguished from the latter by a number of features. Head tilt in central vestibular disease usually is toward the side of the lesion but may be in the opposite direction when the underlying disease involves the cerebellum (paradoxic vestibular syndrome). Similarly, nystagmus may be identical to that seen in peripheral vestibular disease but also may be vertical, diagonal, or different in each eye (disconjugate nystagmus); may change in direction when the position of the head is changed (positional nystagmus); or may be horizontal or rotatory with the fast phase toward the side of the lesion (paradoxic vestibular syndrome). Signs of involvement of the motor and sensory tracts to the limbs as they course through the medulla usually accompany central vestibular disease. Proprioceptive and postural reaction deficits are present in the ipsilateral limbs, together with mild hyperreflexia. The nuclei of cranial nerves V to XII also may be affected by diseases that cause central vestibular lesions. Signs of cranial nerve dysfunction accompanying vestibular abnormalities, other than that of the facial nerve alone, indicate central vestibular disease. Horner's syndrome, however, is not seen in conjunction with central vestibular disease. Decreased mentation often occurs in animals with central vestibular disease, in contrast to the normal mental status of animals with peripheral vestibular lesions.

Animals with either peripheral or central vestibular lesions tend to lean against the walls and may fall when forced to perform a complex motor maneuver. They may adopt recumbency with the lesion side directed down and have poor righting responses, particularly from lesion-side-down recumbency. When positioned so that the lesion side is directed up, they often will roll to a lesion-down position. Blindfolding the patient eliminates visual compensatory mechanisms and therefore increases the severity of the clinical signs (Romberg test). Blindfolding may help in the detection of subtle lesions but should be done with caution because it may result in falling. Animals with vestibular disease occasionally may have slight ventral strabismus in the ipsilateral eye and slight dorsal strabismus in the contralateral eye. This strabismus can be differentiated from the ventrolateral strabismus seen with lesions of the oculomotor nerve because the strabismus accompanying vestibular lesions is mild and changes or disappears when the head position is changed. The strabismus in animals with paralysis of the oculomotor nerve does not change as the head position is altered. In the cow and sheep, evaluation of globe position must be conducted with the head held in normal position because these animals rotate the globe downward when the head and neck are extended. Conversely, the globe is maintained in the center of the palpebral fissure at all head positions in the horse and the goat.

Animals with bilateral vestibular lesions do not have head tilt or nystagmus. The animal stands with the legs base-wide and may fall to either side when the head position is rapidly altered. Affected animals may show a coarse side-to-side head tremor. Bilateral vestibular lesions usually are peripheral in type and are rarely encountered in clinical practice. Central lesions extensive enough to cause bilateral vestibular disease are likely to be fatal.

8.5.5 Incoordination, Hypermetria, Dysmetria, and Intention Tremor

Clinical signs that occur in animals with cerebellar disorders include hypermetria, intention tremor, and truncal ataxia (excessive body sway during movement along a straight path). Conscious proprioceptive fibers do not pass through the cerebellum. Consequently, postural placement of the limbs is normal. Animals with cerebellar disease move the limbs with excessive rate, range, and force. There is a slight delay in lifting the limb from the ground. At the peak of protraction the limbs are lifted too high and too far anteriorly. The legs then hit the ground with excessive force. When the animal is turned, the legs circumduct. The animal may violently thrust the outside rear limb backward and laterally when turned. The forelimbs and the hindlimbs occasionally collide during the turn (interference). At rest the animal stands with the legs abducted, in a base-wide stance. This is not a conscious proprioceptive deficit, however, because the animal consciously returns the limbs to the base-wide posture if the leg position is manually corrected. There is intention tremor, most marked in the head. When the animal attempts to reposition the head, it overshoots the intended position, corrects, and then overshoots again.

The sequence of overcompensation and overcorrection results in a coarse oscillation. The head tremor is most conspicuous when the animal is alert, especially when eating. Intention tremor disappears when the animal is recumbent and the musculature is relaxed. In animals with cerebellar disorders, the extensor muscles of the limbs may be hypertonic, and spinal reflexes occasionally are exaggerated. Foals with cerebellar disease fall backward. This does not usually occur in ruminants. Lesions of the rostral cerebellar vermis can result in opisthotonos. Animals with cerebellar cortical disease may lack a menace response but retain their vision and can negotiate around obstacles. The reason for the menace deficit is unclear, but it is thought to result from disruption of efferent pathways emanating from the occipital (visual) cortex and passing through the cerebellar cortex to the motor nucleus of the facial nerve. Animals with pure cerebellar dysfunction remain bright, alert, and responsive to external stimuli. Animals with very severe lesions of the cerebellum may be recumbent and unable to rise, with decerebellate posture. This posture is characterized by opisthotonos and forelimb extensor rigidity, with normal or flexed hindlimbs. Unlike decerebrate rigidity, animals in decerebellate rigidity have normal mentation and a good prognosis if the underlying disease is not progressive. Cerebellar disease is often bilaterally symmetric, but lateralized lesions cause signs on the ipsilateral side of the body. Diseases that cause spasticity or tremors in livestock are listed in Table 8-9.

Involvement of the vestibular components of the cerebellum (caudal cerebellar peduncle, flocculonodular lobe, and fastigial nucleus) results in signs of paradoxic vestibular syndrome, described earlier.

8.5.6 Abnormalities of Cranial Nerve Function

The normal functions of the cranial nerves are described earlier, in the discussion of the neurologic examination. Cranial nerve dysfunction may be central or peripheral in type, depending on whether the neurologic lesion lies within the central components of the cranial nerves within the brain or in the peripheral portions of the nerves. Clinical signs of cranial nerve dysfunction are ipsilateral to the lesions that cause them.

8.5.6.1 BLINDNESS, STRABISMUS, OCULAR PARESIS OR PARALYSIS, ABNORMALITIES OF PUPIL SIZE OR PUPILLARY LIGHT REFLEXES

Lesions involving cranial nerves II, III, IV, and VI are described earlier, in the discussion of blindness and other visual dysfunctions.

8.5.6.2 FACIAL HYPOESTHESIA OR ANALGESIA, DROPPED JAW

Loss of or decrease in sensory perception on the face, including the inside of the mouth, the nasal planum, the cornea, and the lower jaw area is the result of lesions of the trigeminal nerve. It is important to distinguish this from the signs of contralateral cerebral disease or facial nerve paralysis. In the former case conscious perception of the stimulus is decreased, but animals will respond to vigorous or painful stimuli and usually will blink in response to corneal stimulation. Animals with cerebral disease have decreased mental alertness and may have other signs of cerebral disease, such as seizures, circling, or contralateral hemiparesis. Facial nerve lesions result in an inability to move the muscles of facial expression or blink on the affected side, but animals will avoid stimulation of the face by pulling away the head and neck in a coordinated fashion. Unilateral loss of facial sensation most commonly results from damage to the peripheral portion of the trigeminal nerve, the trigeminal ganglion in the petrosal bone of the skull. Bilateral facial hypoesthesia is most likely caused by cerebral disease rather than trigeminal nerve disease. The mandibular branch of the trigeminal nerve also carries motor innervation to the muscles of mastication from the pontine motor nucleus of the trigeminal nerve. Bilateral involvement of the motor component of the nerve results in a dropped jaw and

inability to prehend and chew food, together with drooling saliva. The muscles of mastication atrophy, most obvious in the masseter and temporalis muscles. Unilateral disease causes atrophy of the denervated muscles, and mild jaw weakness may be appreciated, but the animal can still eat and close the jaw. The most important differential diagnosis for dropped jaw is rabies. A careful history must be taken to ascertain the risk of exposure to this disease as well as whether the animal has been vaccinated. Central lesions in the trigeminal nerve also may involve adjacent structures in the brainstem, such as the facial nerve, the vestibular system, and the long sensory and motor tracts to the limbs.

Table 8-9 Diseases of Spasticity or Tremors in Horses and Ruminants

Disease	Clinical Manifestations	Affected Species
Cerebellar hypoplasia Bovine viral diarrhea Bluetongue Akabane Border disease Wesselbron disease Hereditary	Intentional head tremor, base-wide stance, hypermetria, hypertonia, hyperreflexia, truncal ataxia, menace deficit, opisthotonos	Cattle, sheep, goats
Cerebellar abiotrophy	Intentional head tremor, base-wide stance, hypermetria, hypertonia, hyperreflexia, truncal ataxia, menace deficit, opisthotonos	Cattle, horses
Daft lambs	Recumbency, hypertonicity, hyperreflexia, deafness, intentional head tremors, hypermetria	Sheep
Grass staggers Bermuda Kikiyu Rye grass Mycotic tremorgens Canary Dallis	Hypermetria, hyperreflexia, truncal ataxia, head tremors, base-wide stance, recumbency, ptyalism, hyperexcitability, hyperesthesia	Cattle, sheep, goats
Hypomagnesemia	Hypermetria, hyperreflexia, truncal ataxia, recumbency, hyperesthesia, menace deficit, opisthotonos, aggressiveness, hypertonia	Cattle, horses
Lysosomal storage disease	Intentional head tremor, base-wide stance, hypermetria, hypertonia, hyperreflexia, truncal ataxia, menace deficit, opisthotonos, blindness, aggressiveness	Cattle, goats
Locoism and *Swainsonia* poisoning	Ataxia, conscious proprioceptive deficit, obtundation, intentional head tremor, loss of herd instinct, maniacal behavior, flaccidity of the nose and lips, base-wide stance	All species
Aspergillus clavatus toxicosis	Ataxia, weakness, muscle tremors, hypersalivation, altered behavior, recumbency, opisthotonus, death	Cattle, sheep
Hereditary neuraxial edema	Recumbency, head tremor, good appetite, hyperesthesia, nystagmus, strabismus, muscular fasciculations	Cattle
Bovine familial convulsions and ataxia	Tetaniform seizures, ataxia, hypermetria, hyperreflexia, head tremors, truncal ataxia	Cattle
Maple syrup urine disease	Obtundation, recumbency, opisthotonos, stimulus-induced tetanic spasms, convulsions, generalized decrease of spinal reflexes	Cattle
Solanum dimidiatum	Head tremors, hypermetria, hypertonia, hyperesthesia, weight loss, opisthotonos, recumbency, and convulsions	Cattle

8.5.6.3

FACIAL PARESIS OR PARALYSIS

Lesions of the facial nerve result in ipsilateral atonia or hypotonia of the facial muscles. The clinical signs of facial nerve paralysis in all large animals include ptosis, dropped ear, and absence of the menace response and palpebral reflex. There is accumulation of food in the cheek pouch and commissure of the lips on the ipsilateral side. Affected animals frequently drool saliva from the lip commissure on the affected side. The animal is unable to open the nostril on the affected side during inspiration. The muzzle of the horse, goat, and sheep deviates away from the direction of the neurologic lesion. Deviation of the muzzle is not seen in cattle because of the normal rigidity of the planum nasale. If the neurologic lesion is located between the medulla oblongata and the skull, the ipsilateral eye may be dry because of loss of innervation from the parasympathetic nucleus of cranial nerve VII. Lesions of the central components of the facial nerve in the medulla oblongata also destroy proprioceptive tracts and reticular system neurons, resulting in conscious proprioceptive deficits and, sometimes, decreased mentation. Lesions of the peripheral component of cranial nerve VII result in facial atonia or hypotonia but do not produce obtundation or conscious proprioceptive deficits.

140

141

8.5.6.4

HEAD TILT, SPONTANEOUS NYSTAGMUS, DEAFNESS

Lesions involving cranial nerve VIII, the vestibulocochlear nerve, produce signs of vestibular dysfunction, as described previously. Deafness also may be a consequence of vestibulocochlear nerve disease. Bilateral deafness has been reported in Paint horses, where it may be a heritable defect associated with the gene for white coat color, similar to the situation that exists in a number of breeds of dogs with white or merle coat color. Deafness also can result from severe aural disease. Although bilateral deafness is fairly easy to recognize clinically, unilateral deafness may be less obvious. Inability to localize sound occurs when animals have unilateral deafness and may be suspected when animals alert to sound but do not turn toward the sound. Auditory evoked potentials can be used to determine integrity of the auditory pathway in the inner ear and medulla oblongata.[53]

8.5.6.5

DYSPHAGIA, DYSPHONIA, STERTOROUS BREATHING

Lesions in the nucleus ambiguus (cranial nerves IX, X, and XI) produce dysphonia, inspiratory dyspnea, dysphagia, and neurogenic atrophy of the trapezius, sternocephalicus, and brachiocephalicus muscles. The inspiratory dyspnea is characterized by roaring and snoring. Roaring is a stertor that is made during peak inspiratory flow. It is caused by paralysis of the cricoarytenoideus dorsalis muscle, resulting in a failure to abduct the arytenoid cartilages during inspiration. Additional evidence of paralysis of cranial nerves IX to XI may be obtained by endoscopic examination of the pharynx. Other signs of paralysis of cranial nerves IX to XI include failure to abduct the vocal folds, collapse of the pharynx, dorsal displacement of the soft palate, and inability to swallow a nasogastric tube. Lesions in the peripheral parts of the glossopharyngeal, vagus, and accessory spinal nerves produce similar laryngeal signs but may be differentiated from centrally located lesions by attitude, appetite, and conscious proprioceptive responses. Animals with peripheral nerve deficits remain alert and appetent and do not show conscious proprioceptive deficits, whereas animals with centrally located lesions may be depressed and inappetent and may have proprioceptive and postural deficits. Animals with bilateral lesions in the peripheral nerves are unable to open the glottis during inspiration and display extreme respiratory distress. Peripheral lesions of the accessory nerve that have been present for longer than 1 month may produce neurogenic atrophy of the trapezius, brachiocephalicus, and sternocephalicus muscles. This is frequently accompanied by aspiration pneumonia. Lesions of the visceral efferent component of cranial nerve X in ruminants produce vagal indigestion, which is characterized by ruminal distention with fluid,

ruminal tympany, abomasal stasis, and sometimes a hypochloremic, hypokalemic metabolic alkalosis. This is an important disease of the ruminant gastrointestinal tract. Hypoglossal nerve lesions produce a weak or flaccid tongue. In animals with unilateral lesions, the tongue deviates away from the side with the lesion and is flaccid when it is manually extended from the mouth. After prolonged denervation (1 month or more) the ipsilateral side of the tongue atrophies and the tongues deviates toward the affected side. Horses with lesions in the sensorimotor cortex may also fail to retract the tongue normally; however, the tongue tone is variable, and the animal can retract it if it receives sufficient stimulation. In comparison, the tongue tone is consistently weak in cases of hypoglossal paralysis.

Signs of cranial nerve dysfunction, together with the central origins or projections of the nerves, are summarized in Table 8-10. Diseases that involve the brainstem and cranial nerves are summarized in Table 8-11.

141

Lesions of the medulla oblongata can produce severe obtundation, somnolence, or coma as a result of ARAS dysfunction in addition to signs of vestibular dysfunction and functional deficits in cranial nerves V to XII. Other clinical signs of medullary lesions include ipsilateral paresis and conscious proprioceptive deficits as a result of dysfunction in the rubrospinal, reticulospinal, spinothalamic, and spinocerebellar pathways. The spinal reflexes of the ipsilateral limbs are exaggerated, and the extensor muscle tone is increased. Further details are given in the discussion of quadriparesis and hemiparesis, later.

143

Table 8-10 Clinical Signs of Cranial Nerve Dysfunction

Cranial Nerve	Central Origin or Projection	Clinical Signs of Dysfunction	Comments
I—Olfactory	Olfactory bulb, limbic system (behavior and emotion centers), cerebral cortex	Loss of sense of smell (anosmia)	Olfactory nerve lesions are rare and difficult to detect clinically.
II—Optic	Optic chiasm, optic tract, lateral geniculate nucleus, optic radiation, occipital cortex	Blindness	See text for additional comments (blindness).
III—Oculomotor	Midbrain somatic and parasympathetic nuclei	Ventrolateral strabismus, ptosis (somatic component); dilated, nonresponsive pupil (parasympathetic component)	
IV—Trochlear	Midbrain	Dorsomedial strabismus	Trochlear nerve lesions are rare and usually accompanied by other signs of midbrain dysfunction.
V—Trigeminal	Pons (motor nucleus), medulla, and rostral cervical spinal cord (sensory tract)	Dropped jaw in bilateral motor paralysis; decrease or loss of sensation to most of the structures of the head and face in sensory nerve disease	Rabies is an important differential diagnosis in animals with a dropped jaw.
VI—Abducent	Rostral medulla oblongata	Medial strabismus (paralysis of the lateral rectus muscle)	
VII—Facial	Medulla oblongata (rostral to middle); motor, sensory, and parasympathetic components	Facial paresis to paralysis (motor component); loss of sense of taste to rostral two thirds of the tongue, loss of sensation on medial aspect of the pinna (sensory components); decreased tear production (dry eye) and decreased salivation (parasympathetic components)	The facial nerve is particularly susceptible to damage in its peripheral course because of its proximity to the middle ear and to the guttural pouch in horses and its superficial location on the face.
VIII—Vestibulocochlear	Medulla oblongata (middle)	Decreased hearing or deafness; vestibular signs (head tilt, nystagmus, falling, rolling)	See description of vestibular disease in text.

IX, X, XI—Glossopharyngeal, vagus, accessory	Medulla oblongata (nucleus ambiguus in middle to caudal medulla and rostral cervical spinal cord)	Dysphagia (IX and X), laryngeal paresis to paralysis (X), atrophy of sternocephalicus, brachiocephalicus, and trapezius muscles (XII)	Rabies is an important differential diagnosis in animals with dysphagia or choke.
XII—Hypoglossal	Medulla oblongata (middle to caudal)	Paresis to paralysis of the tongue	Acute unilateral lesions result in the tongue being deviated away from the side of the lesion. In chronic disease, atrophy and contracture of the affected side of the tongue result in deviation toward the affected side.

Table 8-11 Diseases of the Brainstem and Cranial Nerves

Disease	Location	Clinical Signs and Laboratory Findings
Viral encephalomyelitis, rabies, malignant catarrhal fever (cattle only)	Multifocal brainstem, particularly medulla oblongata	Head tilt, nystagmus, circling, ataxia, proprioceptive deficit, tongue paralysis, anisocoria, dilated nonresponsive pupils, strabismus, paralyzed tongue, dysphonia, dysphagia, plus cortical signs (rage, fright, fear, convulsions); CSF may show pleocytosis (mainly mononuclear cells); high protein
Listeriosis (cattle)	Multifocal brainstem, particularly basal ganglia, metencephalon, and medulla oblongata	Circling, head tilt, facial paralysis, roaring, snoring, dysphagia, obtundation, coma, convulsions, ataxia, proprioceptive deficit; CSF shows pleocytosis (mainly mononuclear); increased protein
Thromboembolic meningoencephalomyelitis (cattle)	Multifocal brainstem and cortex	Circling, nystagmus, head tilt, strabismus, tongue paralysis, dysphagia, facial paralysis, coma, convulsions, obtundation, xanthochromic CSF with increased neutrophils
Peripheral vestibular disease	Petrous temporal bone, membranous labyrinths, vestibulocochlear nerve, also associated with facial nerve paralysis	Head tilt, circling, or leaning toward lesion side, ventrolateral strabismus on ipsilateral side, dorsomedial strabismus on contralateral side, nystagmus (usually horizontal and constant)
Verminous migration	Multifocal brainstem, most commonly thalamus, diencephalon	Circling, nystagmus, head tilt, strabismus, tongue paralysis, facial paralysis, obtundation, coma, convulsions, depression, proprioceptive deficit, bradycardia, salivation, head pressing, hemianopsia; high protein and increased WBCs in CSF
Space-occupying mass Tumor Abscess	Cerebellopontine angle; cranial nerves V, VII, and VIII	Head tilt, strabismus, proprioceptive deficit, facial analgesia, jaw drop, obtundation, coma, strabismus, nystagmus, hyperreflexia, hypertonia, falling or circling toward affected side, blindness on contralateral side, tongue paralysis, hemianopsia, bradycardia, coma, convulsion
Horner's syndrome	C8 to T1 motor neurons (gray matter), spinal roots, vagosympathetic trunk, sympathetic tracts of spinal cord, periorbita	Miosis, enophthalmos, lack of nasal sweat (cattle only), ipsilateral facial swelling (horses only)
Guttural pouch mycosis (horses)	Guttural pouch	Dysphagia, head shyness, head shaking, roaring, dysphonia, protrusion of the tongue from the mouth, epistaxis, head tilt, nystagmus, facial sweating, shivering, Horner's syndrome, colic, facial paralysis

CSF, Cerebrospinal fluid; *WBCs*, white blood cells.

8.5.7 Measurement of Brainstem Function Using Auditory Evoked Potentials

The integrity of the vestibulocochlear apparatus can be examined using brainstem auditory evoked potentials.[53–55] This method examines the averaged waveform that is generated after an auditory click in the ear. The individual signals from a single click stimulus are small and therefore must be amplified by repeating the stimulus (30 to 100 dB, 10 Hz) between 30 and 1000 times and recording the voltage difference between two electrodes placed on the head. The recording electrode is usually placed over the petrous temporal bone, and the reference electrode at the vertex, or elsewhere on the head. The technique of signal averaging is used to eliminate background electrical activity and enhance the specific waveforms generated by the auditory impulse. The response usually is measured for 10 ms after the stimulus is applied. Ablation of the entire cochlear apparatus and vestibular nerve, as might occur with otitis interna, would result in a loss or attenuation of waveform activity after the click stimulus. Injury to the brainstem vestibular nuclei would result in a loss of waves II through VI. Damage to the trapezoid body (pons), lateral lemniscus, caudal colliculus, and medial geniculate body would result in a loss of waveforms III through VI, respectively. Increased latency between the peaks is usually associated with toxic or degenerative diseases of the CNS.

8.5.8 Paresis and Ataxia in Two or Four Limbs

Quadriparesis and hemiparesis are seen with lesions affecting the mid to caudal brainstem (midbrain, medulla oblongata) or the cervical spinal cord (C1 to T2 spinal cord segments). Quadriparesis also can be seen in generalized peripheral nerve or muscle disease, discussed later. Paraparesis results from disease affecting the spinal cord between segments T3 and L2 or the peripheral nerves to the hindlimbs. Disease of the cerebrum and thalamus does not produce appreciable paresis and ataxia when the animal is walking in a straight line on a level surface, but these signs become apparent in the limbs contralateral to the lesion when the animal is asked to circle, back, step over obstacles, or walk on a slope. Localization of the lesion when signs of paresis and ataxia are present depends on the assessment of muscle mass and tone, spinal reflexes, and evaluation of brainstem function, as determined by the presence or absence of signs such as altered mentation, cranial nerve deficits, or vestibular dysfunction.

Quadriparesis and ataxia with normal muscle mass and tone and normal to increased spinal reflexes indicate a lesion in the brainstem or in spinal cord segments C1 to C5. Presence of clinical signs of brain disease will facilitate localization of the lesion to an intracranial site, as described earlier. Lesions in the midbrain cause contralateral postural and proprioceptive deficits, whereas those in the medulla oblongata cause ipsilateral signs. Cerebellar disease causes a truncal ataxia, without significant loss of proprioceptive or postural functions, and with no or mild hyperreflexia of the limbs. Lesions of the thalamus and cerebrum cause minimal to no paresis or ataxia when the animal is gaited on a level surface, but contralateral proprioceptive and postural reaction deficits are present. Altered mentation and other signs of cerebral or thalamic disease are expected, such as circling or cortical blindness. Animals with spinal cord disease have normal mentation. The clinical signs shown by such patients depend on the location of the lesion and the relative amount of damage to gray (cell bodies) and white (myelinated spinal cord tracts) matter. Loss of white matter results in sensory loss, whereas gray matter damage produces lower motor neuron deficits. The sensory losses are either proprioceptive responses or cutaneous sensory deficits. White matter is usually more susceptible to pressure changes than gray matter, so proprioceptive deficits are consistently observed during the first stages of spinal cord disease. Spinal cord diseases may be localized to one of the following five regions: high cervical (C1 to C5), cervicothoracic (C6 to T2), thoracolumbar (T3 to L2), lumbosacral (L3 to S2), and sacrococcygeal (S3 to Cd5) regions. Tables 8-4 and 8-5 list the peripheral nerves and the spinal segments that innervate them.

8.5.9 Cervical Spinal Cord

Animals with incomplete section of the cervical region of the spinal cord display hemiparesis or tetraparesis. The clinical signs include knuckling, stumbling, failure to lift the inside feet when turned in a tight circle, interference, hypermetria, abnormal postural placement responses, crossing over midline when turned, and excessive truncal sway. Animals with more severe lesions of the cervical spinal cord become recumbent and are unable to lift the head from the ground. There is an asymmetric righting response in animals with unilateral lesions. They can raise the head and neck to a variable distance only when lying with the lesion side facing down. Muscle tone and spinal reflexes in the limbs of recumbent animals are exaggerated. The urinary bladder is distended. The animals have difficulty urinating, and afterward the bladder contains a large amount of urine. Animals with complete spinal cord transection anterior to C6 die suddenly as a result of paralysis of the intercostal muscles and the diaphragm.

143

144

Lesions between C6 and T2 spinal segments (brachial intumescence) result in conscious proprioceptive deficits in all four limbs and tetraparesis or tetraplegia. There is hypotonia and hyporeflexia of the forelimbs and hypertonia and hyperreflexia of the hindlimbs. Unilateral lesions result in ipsilateral signs. Lesions of C6 to T2 segments involving white but not gray matter do not produce forelimb hypotonia. Conscious perception of painful stimuli may be depressed in all limbs. Flexor reflexes in the forelimbs may be depressed but are normal in the hindlimbs. The righting responses of the head and neck are normal. Urination is difficult, and the urinary bladder is distended and has a large residual volume. After 1 month or more, lesions of the gray matter of the spinal cord or the peripheral nerves may result in neurogenic atrophy of one or more muscle groups of the forelimbs. Gray matter lesions of T1 to T3 spinal segments may result in Horner's syndrome, which is characterized by miosis, enophthalmos, and ptosis in all species. Unilateral facial sweating occurs in horses; lack of sweating on the planum nasale occurs in cattle. Differentiation of high (C1 to C5) and low (C6 to T2) cervical spinal cord lesions may be difficult in horses, especially when signs are fairly mild.

Lesions of the thoracolumbar region (T3 to L3) result in normal activity of the forelimbs and proprioceptive deficits in the hindlimbs. These deficits are similar to those described previously for the cervical areas and include ataxia, knuckling, stumbling, abduction, adduction, interference, excessive truncal sway, and failure to lift the inside foot when pivoted in a tight turn. With complete lesions, the animal becomes recumbent but intermittently assumes a dog-sitting position, with the forelimbs extended and weight bearing and the hindlimbs flexed. Muscle tone and spinal reflexes are exaggerated in the hindlimbs. The urinary bladder is distended, and residual volume is large. The tone of the urethral sphincter is normal. Young animals with severe spinal cord lesions between T2 and L2 display transient hypertonia of the forelimbs (Schiff-Sherrington syndrome). This condition is caused by interference with inhibitory fibers ascending from the lumbar segments in the dorsal funiculi to the lower motor neurons of the forelimbs.[56] These fibers synapse on the neurons of the brachial intumescence. Hypertonia from this deficit may be differentiated from cervical cord lesions by the lack of conscious proprioceptive deficits in the forelimbs of animals with thoracolumbar lesions.

The lumbosacral region (L3 to S2) of the spinal cord contains lower motor neuron efferents to and general proprioceptive afferents from the pelvic limbs. Lesions in this area result in paraparesis or paraplegia. Affected animals are ataxic and have conscious proprioceptive deficits of the hindlimbs. Patients with complete spinal cord lesions of L3 to S2 exhibit flaccid paraplegia, which is accompanied by hyporeflexia or areflexia of the hindlimbs. With prolonged denervation, neurogenic atrophy of the hindlimb musculature occurs.

Lesions located between L3 and L6 spinal cord segments result in urinary bladder distention and maintenance of a large residual volume. The sphincter tone is intact, but urine is not voided unless the intravesicular pressure

exceeds that of the sphincter. These animals usually have contact dermatitis of the perineum and preputial area because of urine scalding. Lesions located around S1 and S2 segments result in bladder distention and flaccidity. Urine may drip continuously from the urethral orifice. The rate of flow may be increased by manually pressing on the bladder during a rectal examination.

Lesions of the sacrococcygeal (S3 to Cd5) region (cauda equina) produce flaccidity of the tail and anus and, in males, paraphimosis. Lesions in this area also result in desensitization of the tail, penis, vulva, anus, and perineum. The urethral sphincter is dilated, and urine constantly drips from the urethral orifice. The animal does not evacuate the bladder and is unable to defecate, resulting in a large dilated urinary bladder and distention of the rectum with feces.

If the entire neurologic lesion is located caudal to S3, ataxia or conscious proprioceptive deficit is not present. The combination of flaccidity of the tail and anus and the constant urine leakage produces contact dermatitis of the perineum and hindlimbs. Perineal scalding is characteristic of lesions of the cauda equina. Specific diseases of the spinal cord, peripheral nerves, and motor end plate are listed in Table 8-12.

Table 8-12 Diseases of the Spinal Cord, Peripheral Nerve, and Motor End Plate of Large Animals

Disease	Signs	Species Affected
Occipitoatlantoaxial malformation	Ataxia, spasticity, hyperreflexia, crepitation or pain with neck flexion, head tilt, torticollis, proprioceptive deficit, visible swelling or asymmetry	Cow, horse
Fractures and dislocations	Tetraparesis, tetraplegia, paraparesis, paraplegia, hyperreflexia, stiff neck, recumbency, proprioceptive deficit, acute death, crepitation, pain, swelling	All species
Cervical spinal abscesses	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, stiff neck, proprioceptive deficit, sudden death, crepitation, pain, swelling	All species
Myelopathy	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, proprioceptive deficit	Horse
Cervical stenotic myelopathy	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, stiff neck, proprioceptive deficit, strip sweating	Horse
Cervical vertebral instability	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, stiff neck, proprioceptive deficit, sudden death, crepitation, pain	Horse
Spinal tumor (lymphosarcoma, neurofibroma)	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, proprioceptive deficit	All species
Equine rhinopneumonitis	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, proprioceptive deficit, flaccid anus, flaccid tail, dysuria, distended bladder, impacted rectum, urine scalding	Horse
Copper deficiency	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, proprioceptive deficit	Sheep, goat
Cauda equina neuritis	Pruritus in perineum, hair loss in perineum, analgesia in perineum, flaccid tail, flaccid anus, paraphimosis, dysuria, facial palsy, head tilt, leaning, nystagmus	Horse
Ischemic myelopathy (fibrocartilaginous embolism)	Paraplegia, tetraplegia, flaccid tail, flaccid anus, areflexia at site of lesion, hyperreflexia distal to site of lesion, proprioceptive deficit	Horse, sheep
Postanesthetic myelopathy	Paraparesis to paraplegia, ataxia, hypoalgesia, scoliosis	Horse, cattle (calf)
Caprine arthritis-encephalitis virus	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, proprioceptive deficit	Goat

144

145

Segmental myelitis	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, stiff neck, proprioceptive deficit, strip sweating, hyporeflexia, areflexia, lower motor neuron deficit, facial nerve paralysis, jaw drop	Horse
Developmental defects (spina bifida, Arnold-Chiari syndrome, syringomyelia, hemivertebrae, spinal cysts)	Paraplegia, paraparesis, tetraplegia, tetraparesis, hypotonia, atonia, neurogenic atrophy, torticollis, scoliosis, kyphoscoliosis, misshapen tail, absence of skin over dorsal midline	All species
Verminous migration	Tetraparesis, tetraplegia, paraparesis, paraplegia, recumbency, proprioceptive deficit, head tilt, hyporeflexia, areflexia, hyperreflexia, hypertonia, hypotonia	All species
Tetanus	Stiffness, normal reflexes, flashing third eyelid, trismus, bloat, convulsions, coma, raised tail head	All species
Botulism	Flaccidity, ataxia, dysphagia, hyporeflexia, pupillary dilation, facial hypotonia, flaccid tail, flaccid anus	All species
Progressive ataxia	Ataxia, conscious proprioceptive deficit, recumbency	Charolais cattle
Locoism	Ataxia, conscious proprioceptive deficit, recumbency, bizarre behavior	All species
Dying back axonopathies	Hypermetria, hyperreflexia, proprioceptive deficit, flaccid tail, anus, fecal and urine retention, urine scalding, recumbency	All species
Elso heel (spastic paresis)	Affected hindlimb is hyperextended and swings in pendulum fashion; tail head is elevated	Cow
Spastic syndrome (crampy)	Episodic hyperextension of the hindlimb, extension of the limb behind the cow, head and neck extension	Cow
Peripheral nerve injuries	Areflexia, hypotonia, hyporeflexia, atonia, anesthesia, analgesia of a specific area of limbs or trunk, inability to support weight, normal function of limbs distal to denervated site	All species
Ionophore toxicosis (salinomycin, lasalocid, monensin)	Tetraparesis, tetraplegia, ataxia, conscious proprioceptive deficit, colic, cardiac dysrhythmia, sudden death	All species
Periodic hyperkalemia	Episodic tremors, weakness, spasticity during episodes, recumbency	Horse, cow
Myotonia congenita	Episodic weakness, spasticity during episodes	All species
Bromide intoxication	Weakness, ataxia, stumbling, proprioceptive deficit, closed eyelids, drooped head and neck, paraphimosis	Horse
Coyotillo poisoning	Progressive weakness, hypermetria, areflexia	Goat
Humpy back/Coonabaran disease	Arched back, ataxia, conscious proprioceptive deficit, hindlimb stiffness, recumbency	Sheep

Neosporosis	Recumbency, ataxia, conscious proprioceptive deficit, neurogenic atrophy	Calf	
Cycad palm poisoning	Posterior paresis, conscious proprioceptive deficit, elevated tail head, paraparesis, paraplegia	Cow	
Acquired torticollis	Abnormally positioned head and neck	All species	145
Sorghum toxicosis	Ataxia, paraparesis, paraplegia, rabbit-hopping gait, proprioceptive deficit, recumbency, weight loss	Horse, cow	146
Stringhalt	Normal at rest, involuntary hyperflexion of the hock and stifle	Horse	
“Kangaroo” gait	Forelimb weakness, ataxia, proprioceptive deficits (bilateral radial nerve paralysis)	Sheep	
Tick paralysis	Progressive generalized paresis, ataxia, recumbency, flaccid tail, flaccid anus, weak facial muscles	All species	

8.5.10 Muscle Atrophy, Reduced Muscle Tone, Flaccid Paresis, Focal Analgesia

Clinical signs of reduced muscle tone, muscle atrophy, and flaccid paresis indicate peripheral nerve, muscle, or neuromuscular diseases. Signs may be localized to a single limb, as in the case of traumatic peripheral nerve injury; generalized, as in botulism and many myopathies; or multifocal, as in equine protozoal myeloencephalitis and other diseases that attack multiple areas of the CNS, destroying the ventral horn gray matter of the spinal cord, or nuclei of cranial nerves in the brainstem. Details of neuromuscular diseases and the use of ancillary diagnostic testing to localize peripheral nerve, muscle, and neuromuscular disease are described in Chapter 35.

Peripheral nerve lesions, whether of the central components of the nerves in the spinal cord and brainstem or along their peripheral course in the limbs and head, also can result in focal hypalgesia or anesthesia. Knowledge of the autonomous zones for the peripheral nerves innervating the limbs can be used to localize such peripheral nerve lesions.

8.5.11 Urinary Incontinence and Urine Retention

The clinical signs of urinary bladder denervation are variable and depend on the lesion location. Lesions of the sacral segments of the spinal cord produce a flaccid bladder, which distends with a large residual volume. Spontaneous urine leakage occurs continuously from the urethra. Additional urine flow occurs when the abdominal pressure is increased. The urethral sphincter is dilated and atonic. Lesions of the brainstem or spinal cord anterior to S1 produce reflex dyssynergia, a disturbance in coordination of micturition, wherein the facilitatory influence of the bladder stretch receptor (afferents) maintains tonic activity on the efferents of the urethral sphincter. The lack of inhibition of these reflexes from the upper motor neuron pathways produces hypertonicity of the urethral sphincters and results in an impediment to urine flow. There is a high intravesicular pressure and a large postvoiding urine volume. The urine escapes paroxysmally only when the intravesicular pressure exceeds the sphincter pressure. After approximately 1 month of denervation, local spinal reflexes between the sacral afferent and efferent neurons develop in the S1 to S5 segments, and incomplete voiding occurs. In these cases the residual volume remains large, and the normal urination posture is not attained.

9 Chapter 9 Alterations in Body Weight or Size

John Maas

Meri Stratton-Phelps

Slowed growth and below-normal weight gain usually happen at the same time, although occasionally they develop separately. By definition a decrease in growth and weight gain is limited to the growing animal. Similar pathogenic mechanisms cause weight loss or an emaciated condition in an adult patient. This arbitrary age division allows the clinician to consider possible causes that are more or less common for a given age-group.

Potential growth and weight gain are genetically determined. They differ according to species, breed, and sex, and marked differences in potential growth exist within a breed. The potential for growth in ruminants is greater in the offspring of multiparous females than in those from primiparous females. The normal or minimum growth and weight gain rates for common breeds of the various large animal species are outlined in the section on assessment of growth and weight gains.

9.1 MECHANISMS OF DECREASED GROWTH AND DECREASED WEIGHT GAIN

Major pathogenic mechanisms that result in decreased growth and decreased weight gain include the following:

- Inadequate dietary intake of essential nutrients
- Infections or inflammation
- Parasitism
- Genetic errors in metabolism or physiologic function
- Concurrent toxicosis
- Environmental causes
- Multiple causes

Inadequate intake of one or more essential nutrients is an important cause of decreased growth. In many cases growing animals are not provided with a sufficient volume of feed to meet their nutrient requirements. Young animals rely on a highly digestible diet that provides energy and essential nutrients for growth. Even animals fed an appropriate volume of a poor-quality milk replacer could suffer from poor growth. Milk replacers formulated with sources of protein, fat, vitamins, and minerals that have limited nutrient digestibility may induce a state of energy, protein, vitamin, or mineral malnutrition. For some young animals, poor-quality forage is the only feed available. Weaned foals and ruminants rely on forages and cereal grains to provide essential nutrients. Hay that has been harvested at a late stage of growth usually has a lower nutrient digestibility compared with young forages. Diets low in digestible energy or protein or both reduce total daily intake in ruminants (Table 9-1) because of the increased turnover time ($T_{½}$) in the gastrointestinal tract and subsequent decreased throughput. This compounds the problems caused by an inadequate intake of digestible nutrients. The digestibility of forages is even lower for horses than for ruminants.

Protein-calorie malnutrition (PCM) is the most common clinical cause of decreased growth and decreased weight gain in young animals. It is characterized by smaller size and lower weight than the normal minimums for age, breed, and sex. Inadequate intake of digestible energy and protein (or essential fatty acids in the neonate primarily adapted to a milk diet) results in inadequate levels of amino acids, fats, and carbohydrates for normal metabolism and growth. Diets that lack any of the other essential nutrients (fatty acids, vitamins, macrominerals, or trace minerals) can also decrease growth. Deficiencies of calcium, phosphorus, and magnesium result in improper skeletal formation. Deficiencies in other macrominerals (e.g., sodium, chloride, potassium), trace minerals (e.g., copper, zinc, manganese, cobalt, iron), and vitamins (e.g., A, D, E, thiamin) cause biochemical dysfunctions that lead to inefficient metabolism and growth. Large animal patients that grow slowly as a result of inadequate diets often have normal or increased appetites until they are terminally ill. Physical findings and clinicopathologic data from animals with PCM often are within the normal range until the disease process is well advanced.

Infections or inflammatory processes are important causes of decreased growth and decreased weight gain in young horses and ruminants. The decrease in growth can be of short duration followed by recovery and compensatory gain (cryptosporidiosis) or can persist (chronic bronchopneumonia). Infections or inflammatory processes can also result in nutrient malabsorption (chronic salmonellosis, acute rotavirus diarrhea), anorexia (pharyngeal abscesses), increased nitrogen turnover, and direct protein losses (gastrointestinal disease). Energy or protein requirements may be increased as a result of infection and inflammation.

147

148

Table 9-1 Maximum Dry Matter Intake (DMI) Related to Forage Quality for Cattle

Forage Quality	Maximum DMI/Day (% Body Weight)	Maximum DMI for 500 kg/Cow/Day (kg)
Poor	1–1.5	5–7.5
Oat straw		
Corn stover		
Average	2	10
Meadow grass hay		
Excellent	2.5	12.5
Alfalfa hay (25% crude fiber)		
Corn silage		

From Maas J: Relationship between nutrition and reproduction in beef cattle, *Vet Clin North Am*, 3:634, 1987.

Parasitism often affects young horses and ruminants and results in decreased growth and decreased weight gain by increasing nutrient requirements, increasing nutrient losses, and/or decreasing nutrient absorption. The animal's metabolic rate and nutrient requirements may also increase as a result of inflammatory and immune reactions that arise secondary to parasitism.

Genetic diseases (α-mannosidosis, dwarfism) result in decreased growth through generalized errors in the genetic code or interference with strategic reactions in one or more metabolic pathways. Congenital cardiac malformations (tetralogy of Fallot, interventricular septal defect) create physiologic inefficiencies that require energy beyond the body's ability to supply it. Congenital renal disease (agenesis, dysplasia, hypoplasia, polycystic kidney disease)

affects homeostatic mechanisms that regulate electrolyte and acid-base balance, results in the production of uremic toxins, and often results in partial anorexia and PCM. Digestive tract malformations including cleft palate, megaesophagus, and brachygnathism can reduce nutrient ingestion and impair growth.

Toxicities, although rare in growing animals, result in decreased weight gain by interfering with metabolic pathways (e.g., ammonia toxicity, zinc-induced copper deficiency with abnormal skeletal development in foals), by causing loss of body reserves (e.g., thiamin deficiency in horses, bone marrow hypoplasia and associated bleeding diatheses in ruminants associated with bracken fern toxicity), by inducing anorexia, or by a combination of mechanisms. The pathogenic mechanisms of many toxins are not yet known.

Environmental factors including extreme heat or cold or high humidity result in decreased growth and decreased weight gain. Extremely cold conditions increase an animal's daily energy requirements. During extremely hot weather feed intake often decreases, which may contribute to decreased growth. Often, environmental conditions influence the development of disease, resulting in a subsequent increase in nutrient requirements in a growing animal (e.g., calves with PCM housed in poorly ventilated or overly humid conditions become much more susceptible to infectious pneumonia).

In many cases a combination of these diverse factors may influence the growth and weight gain of young animals. A period of increased growth rate and weight gain, called *compensatory gain*, often occurs after a period of restricted growth. In growing foals, compensatory gain should be closely monitored to prevent excessively rapid growth and abnormal skeletal development.

Boxes 9-1 and 9-2 list many of the possible causes of decreased growth and decreased weight gain in horses and ruminants, respectively.

9.1.1

Box 9-1 Causes of Decreased Growth and Decreased Weight Gain in Horses

9.1.1.1

COMMON CAUSES

Protein-calorie malnutrition (PCM), inadequate nutrient intake

Extreme environmental factors

Parasitism (*Parascaris equorum*, small strongyles, large strongyles, tapeworms, bots)

Bacterial pneumonia *(Rhodococcus equi, Streptococcus zooepidemicus)*, lung abscessation

Viral pneumonia (equine herpes virus, equine influenza)

Gastric ulcers

Lameness (e.g., physitis, osteochondritis dissecans, contracted tendons, osteomyelitis)

Prematurity, dysmaturity

Diarrhea (*Clostridium*, species, *Salmonella*, species, sand enteropathy, other causes)

9.1.1.2 LESS COMMON CAUSES

Esophageal stricture, megaesophagus (idiopathic, acquired)

Peritonitis

Congenital cardiac and great vessel anomalies

Endocarditis

Jaw pain (fracture, dental abnormality)

Cryptosporidiosis

Selenium deficiency

Copper deficiency

Vitamin A deficiency

Vitamin D deficiency

Thiamine deficiency

Phosphorus deficiency

Osteodystrophy

Lead toxicity

Goiter

Generalized steatitis

Rotavirus infection (foals)

Wound myiasis

9.1.1.3 UNCOMMON CAUSES

IgM-deficiency

Combined immunodeficiency disease in foals

Gonadal dysgenesis, intersex (XO, XXY)

Ammonia toxicity

Sarcocystosis

Fluorosis

Congenital renal abnormalities (hypoplasia, dysplasia, agenesis, polycystic kidney disease)

Hydrocephalus

Myeloproliferative disease

Biliary atresia

Hepatic portosystemic shunt

148

149

9.1.2 Box 9-2 Causes of Decreased Growth and Decreased Weight Gain in Ruminants

9.1.2.1 COMMON CAUSES

Protein-calorie malnutrition (PCM)

Mannheima, Pasteurella, Haemophilus, pneumonia

Ostertagiasis I and II

Coccidiosis

Parasitism (flukes, gastrointestinal worms, lungworms)

Salmonellosis

Bovine virus diarrhea

Hepatic abscessation, liver disease

Rotavirus infection

Diarrhea, undifferentiated

Lameness (sole abscess, foot rot, laminitis, foot warts, osteomyelitis)

Cryptosporidiosis

Enterotoxigenic *Escherichia coli*,

Coronavirus

Selenium deficiency

Copper deficiency (molybdenosis)

Sarcoptic mange

9.1.2.2 LESS COMMON CAUSES

Johne's disease

Cardiac or great vessel anomalies

Hydrocephalus

Myiasis

Ammonia (urea) toxicity

Goiter

Eperythrozoonosis

Arthrogryposis

Thiamine deficiency

Cobalt deficiency

Urachal or bladder abscess

Peritonitis

Pharyngeal abscess, injury

Giardiasis

Osteodystrophy, rickets

Neonatal isoerythrolysis

Immune-mediated anemia

Zinc deficiency

Vitamin A deficiency

Adenovirus infection

Tick infestation

Sarcocystosis

Abomasal ulcers

Severe bovine papular stomatitis

9.1.2.3 UNCOMMON CAUSES

Gonadal dysgenesis, intersex

Brisket disease

Epidermolysis bullosa

Phosphorus deficiency

Osteogenesis imperfecta in Friesians

Calf lymphosarcoma

Granulocytopathy

Congenital porphyria

9.1.3

Approach to the Diagnosis and Management of Decreased Growth and Decreased Weight Gain in Horses

1 Take a general history and a diet history.

a General history

i What is the patient's age? Was the foal born prematurely? Were any congenital defects identified during the initial examination of the foal after birth? Did the foal have any complications from sepsis?

ii What is the stocking density of the herd? Is the foal exposed to a high parasite load in the environment? What is the foal's deworming history? Have there been previous problems with gastrointestinal parasitism on the farm? What is the vaccination history of the mare and the foal? Does the farm have a history of infectious disease agents (*Rhodococcus equi, Streptococcus equi*, subsp. *equi*)? Are there any sick horses on the same farm? Has the foal shown any evidence of systemic illness (diarrhea, nasal discharge, cough, pyrexia)?

iii What type of protection is provided from adverse weather conditions? Are there any toxins in the foal's environment?

b Diet history

i If the foal is nursing, what is the weight condition of the mare? Is the mare producing a sufficient amount of milk for the foal? If the foal is an orphan, what type of milk replacer is the owner using? What is the daily energy and protein intake of the foal? Is the owner mixing the solution properly? Does the foal have access to a creep feed? What is the owner using as a creep feed? How much of the creep feed does the foal consume daily?

ii If the foal is a weanling, when was the foal weaned? Does the foal compete with other foals for feed? Has the owner changed the foal's diet recently? If yes, what changes were made? Does the foal have a good appetite? Has the foal's appetite changed recently?

(1) What type of forage is fed to the foal? What is the quality of the forage? Is there gross evidence of dirt, mold, or weed contamination in the forage? Has a hay analysis been performed on the forage? How much forage is offered to the foal (in weight)? How much forage (in weight) does the foal eat each day? 149 150

(2) What type of supplemental feed is fed to the foal? What is the nutrient composition of the supplemental feed? Is the supplemental feed of high quality? How much of the supplemental feed (in weight) does the foal eat each day?

(3) Is the foal offered a vitamin and mineral supplement? Is the vitamin and mineral supplement offered free choice? How much of the supplement (in weight) does the foal eat each day? Could any nutrients be consumed in a toxic amount? Has the owner provided any supplemental parenteral vitamins or minerals to the foal?

2 Perform a physical examination.

a What is the body weight of the foal (measured by using either a scale or weight tape)? What is the body condition score (BCS) of the foal (see Table 9-21)? Is the foal small, thin, or underweight according to growth charts (Table 9-2, Figs. 9-1 and 9-2)?

b Does the foal show any signs of infectious disease (current or resolved)?

c Does the foal have evidence of a congenital abnormality (cardiac, renal, gastrointestinal, oral)?

d Does the foal have any musculoskeletal abnormalities?

3 Examine the feces.

What is the consistency of the feces? Refer to Chapter 20 for the diagnosis and management of neonatal diarrhea; refer to Chapter 7 if the foal is older and has evidence of diarrhea. Is there evidence of sand in the manure? Perform a fecal egg count. If the foal has a positive fecal egg count, follow the parasite control program recommendations in Chapter 49. If a negative fecal egg count is reported but parasitic infestation is still suspected, repeat the test in 2 to 3 weeks or follow the deworming protocols in Chapter 49. Evaluate the feces occult blood. If the foal has a positive fecal occult blood test, review the medical management for melena in Chapter 7.

Table 9-2 Weight as a Percentage of Mature Body Weight in Horses

Age (Months)	Ponies[4] (%)	Light Horses[1–3,5] (%)	Draft Horses (%)
6	55	46	40
12	75	67	57
18	84	80	75

Fig. 9-2 **A** to **C**, Body weight as a percentage of mature body weight for horses at a given age. A modified from Crampton WW: *J Agric Hortic* 26:172, 1923; **B** modified from Lewis LD: *Feeding and care of the horse*, Philadelphia, 1982, Lea & Febiger; **C** modified from Hintz HF: Factors affecting the growth rate of horses, *Horse Short Course Proceedings*, Texas A&M Animal Agriculture Conference, 1979, College Station, Texas.

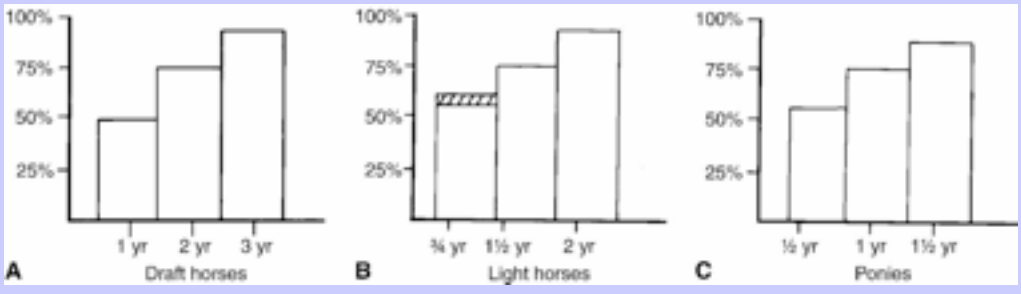

Fig. 9-1 Estimated weight gain of horses of various mature body weights. Modified from National Research Council [NRC]: *Nutrient requirements of horses*, Washington, DC, 1978, National Academy of Sciences, NRC.

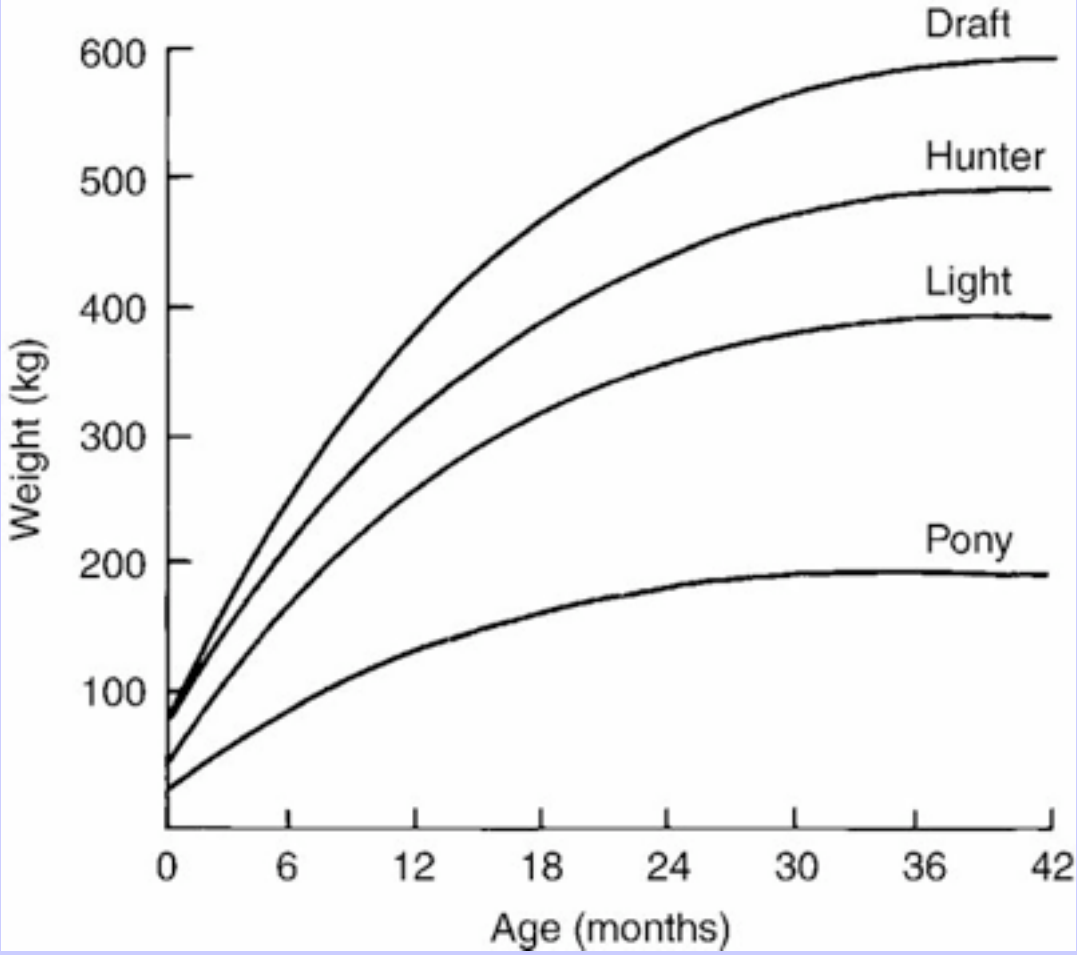

4 Perform blood analyses.

a Perform a complete blood count (CBC) and include a plasma protein and fibrinogen concentration. If the foal is anemic, determine the cause of the anemia following the guidelines in Chapter 24. If the foal's CBC indicates inflammation, review Chapters 25 and 26 and select appropriate ancillary diagnostic tests to identify the source of the infection or inflammation.

b Perform a serum biochemical analysis. Evaluate the results for evidence of systemic disease. Serum albumin is usually within normal limits with PCM until the condition is terminal. Serum glucose is usually normal but it may be decreased in neonatal foals with sepsis. Serum glucose may be elevated in stressed animals. Serum urea nitrogen and creatinine concentrations are elevated in foals with renal disease. Serum urea nitrogen decreases in cases of chronic protein malnutrition.

c If the foal has evidence of systemic disease, perform ancillary diagnostic tests to identify the source of the illness, then manage the case with appropriate medical or surgical intervention.

5 Analyze the diet and improve the feeding program.

a Determine whether the energy, protein, mineral, and vitamin content of the diet meets the requirements of the growing foal (Table 9-3).

i Young horses require adequate levels of essential amino acids for growth. Lysine is the first and threonine is the second limiting amino acid in the equine. Growing foals should consume 4.3% of their crude protein requirement as lysine (multiply the crude protein requirement by 4.3%).[6] Growing foals should also consume at least 0.5% threonine (DM) in their diet. Soybean meal and alfalfa hay contain approximately 3.3% and 0.9% lysine (DM), respectively, whereas cereal grains are poor sources of lysine.

150
152

Table 9-3 Daily Nutrient Requirements for Growth in Equines of Various Mature Body Weights

Mature Body Weight (kg/lb)	Category	Weight		Daily Gain		Digestible Energy (Mcal)	Crude Protein (g)	Lysine (g)	Calcium (g)	Phosphorus (g)
		kg	lb	kg	lb					
Ponies 200 kg (440 lb)	Nursing foal (4 months of age)	67	147	0.34	0.75	5.3	268	11.5	15.6	8.7
	Weanling (6 months of age)	86	189	0.29	0.64	6.2	270	11.6	15.5	8.6
	Yearling (12 months of age)	128	282	0.18	0.40	7.5	338	14.5	15.1	8.4
Horses 400 kg (880 lb)	Nursing foal (4 months of age)	135	297	0.67	1.47	10.6	535	23.0	31.3	17.4
	Weanling (6 months of age)	173	381	0.58	1.28	12.4	541	23.3	30.9	17.2
	Yearling (12 months of age)	257	565	0.36	0.79	15.0	677	21.9	30.1	16.7
Horses 500 kg (1100 lb)	Nursing foal (4 months of age)	168	370	0.84	1.85	13.3	669	28.8	39.1	21.7
	Weanling (6 months of age)	216	475	0.72	1.58	15.5	676	29.1	38.6	21.5
	Yearling (12 months of age)	321	706	0.45	1.0	18.8	846	36.4	37.7	20.9

Horses 600 kg (1320 lb)	Nursing foal (4 months of age)	202	444	1.01	2.22	15.9	803	34.5	46.9	26.1
	Weanling (6 months of age)	259	570	0.87	1.91	18.6	811	34.9	46.4	25.8
	Yearling (12 months of age)	385	847	0.54	1.19	22.5	1015	43.6	45.2	25.1

Modified from National Research Council (NRC): *Nutrient requirements of horses*, Washington, DC, 2007, National Academies Press

9.1.3.0.0.0.0.0.0.0.0.1

Box 9-3 Forage and Large Animal Feed Sampling Instructions

9.1.3.0.0.0.0.0.0.0.0.1.1

SAMPLING PASTURE

1. Collect pasture samples from a 1-foot-square area. Sample only the same type of forage that the horses are grazing. Sample 10 to 20 sites.
2. Using scissors, cut the pasture to within 1 inch of the ground. Do not collect soil-contaminated pasture. Cut all samples to a length of 1 inch, and place all samples into a clean bucket.
3. After sampling is complete, mix the samples well and place the forage into a plastic sealable bag (1-gallon Ziplock). Label the bag with the date of sampling, the collection site, and the owner's name.
4. If the sugar and starch content of the sample is of special interest, the sample should be frozen and shipped on ice to the analysis company.

9.1.3.0.0.0.0.0.0.0.0.1.2

SAMPLING HAY USING A CORE HAY SAMPLER

1. Choose 10 to 20 bales randomly from the hay shipment. Only one type of forage should be submitted for analysis in the same container. If more than one type of hay is analyzed, each should be placed into a separate, labeled plastic bag.
2. Use the core hay sampler with a ratchet brace or drill to collect two samples from each bale. Square bales should be sampled from the long end of the bale. Round bales should be sampled along a horizontal line at the curve of the bale. Place all samples into a plastic sealable bag (1-gallon Ziplock), and label the bag with the date, type of hay, and owner's name.

9.1.3.0.0.0.0.0.0.0.0.1.3

SAMPLING HAY BY HAND

1 Choose 10 to 20 bales randomly from the hay shipment. Only one type of forage should be submitted for analysis in the same container. If more than one type of hay is analyzed, each should be placed into a separate, labeled plastic bag.

2 Open the bale, and divide the bale in thirds. Collect a handful of hay from the center of the bale at each site (two samples per bale). Include everything that you have grabbed (including weeds and other plants) in the sample. Cut all samples to a length of 1 inch, and place all samples into a clean bucket. Thoroughly mix the cut hay samples, place the forage into a plastic sealable bag (1-gallon Ziplock), and label the bag with the date, type of hay, and owner's name. Ensure that all parts of the sample (leaves and stems) are included in the final sample.

9.1.3.0.0.0.0.0.0.0.0.1.4

SAMPLING GRAIN OR PELLETED FEED

1 Analysis of two to four samples from 10 bags is recommended to obtain a representative sample of feed. Only one type of feed should be submitted for analysis in the same container. If more than one type of grain or pelleted feed is analyzed, each should be placed into a separate, labeled plastic bag.

2 Open a bag or a bin, and obtain a 2- to 4-ounce sample from two to four locations in the bag or bin. A sample should be obtained from the bottom of the bin or bag to ensure that a sample of the settled feed is analyzed. When multiple bags or bins are sampled, samples from each bin or bag should be placed into a clean plastic bucket. Once all sampling has been completed, the feed sample should be mixed well, and approximately 1 pound of the feed should be placed into a plastic sealable bag (1-gallon Ziplock). Label the bag with the date, type of feed, and owner's name.

ii Milk replacer

If the foal is consuming a milk replacer, review the guaranteed analysis for the nutrient content of the product. Review the mixing instructions with the owner or farm manager. Develop a feeding program appropriate for the foal's age.

iii Forage

The most accurate way to determine the nutrient content of forage or pasture is with an analysis. Forage sampling instructions and forage analysis companies are listed in Boxes 9-3 and 9-4. University Extension services often provide a forage analysis service. If the client does not purchase a large volume of hay, or if analysis cannot be performed, forage tables from the Nutrient Requirement Council reference books (www.nap.edu) or nutrient tables from the Equi-Analytical Laboratories forage laboratory database (www.equi-analytical.com) can be referenced to estimate the concentration of different nutrients in common forages and supplemental feeds. Use the daily nutrient requirement table (see Table 9-3) to recommend the type and amount of forage the foal should consume based on the nutrient content of the forage.

iv Commercial feeds and grain mixes

The guaranteed analysis on the feed tag label provides the nutrient content of certain ingredients. Contact commercial feed companies for the energy content of their product. Make recommendations about the appropriate use of commercial equine feeds, grain, or grain mixes for young growing foals based on the clinical health of the foal.

v Vitamins and minerals

Ensure that the diet meets the vitamin and mineral requirements of the foal. Supplement the diet if necessary.

b If the foal or weanling has a nutrient deficiency, the problem should be corrected by a change in the diet or through appropriate parenteral supplementation.

c If the diet history indicates that nutrients for maintenance and growth have been steadily consumed, the search for another cause of decreased growth and decreased weight gain should continue.

6 Perform ancillary diagnostic tests.

If the cause of the decreased growth and/or poor weight gain has not been determined, additional diagnostic tests should be performed. Possible tests include, but are not limited to ultrasound, radiographs, serum or whole blood trace mineral analysis, and carbohydrate absorption tests (oral D-glucose, D-xylose).

9.1.4

Approach to the Diagnosis and Management of Decreased Growth and Decreased Weight Gain in Ruminants

1 Take a general history and a diet history.

a General History

i What is the age of the animal? When was a decrease in growth observed? How many animals in the herd are affected? What are the ages of the affected animals? Has the herd had historical problems with growth of the young?

ii Identify the problem as acute, subacute, or chronic.

iii Check for signs or history of previous infectious disease.

iv Determine the parasite control procedures for the animal or herd.

v Examine the environment, including feed preparation areas and equipment, for possible toxic substances (e.g., zinc from galvanized buckets).

b Diet history

i Obtain an accurate diet history, including diet information when a milk or milk replacer diet is being fed (birth to 2 or 3 months of age). Note the age and condition of the dam if patient was suckled before weaning. An accurate postweaning dietary history is essential. Suckled animals are developed ruminants at weaning, but hand-reared animals (dairy calves, bummer lambs, and dairy kids) are usually not fully developed ruminants at the time they are weaned from milk.

ii Inspect all forages and concentrates for quality, signs of spoilage, or abnormal color or odor. Has an analysis been performed on the forage? Is the feed formulated appropriately?

iii Because ruminants are often fed in groups, note whether all animals have adequate space to eat simultaneously.

2 Perform a physical examination.

a Determine the patient's age and weight. Check the patient against age and weight charts (Figs. 9-3 to 9-6).

b Carefully note any signs of infectious or parasitic disease.

c Evaluate the animal for any signs of congenital abnormalities.

Fig. 9-3 Minimum growth curve for dairy heifers. From Sniffen CJ: *Feed Manage* 35:37, 1984.

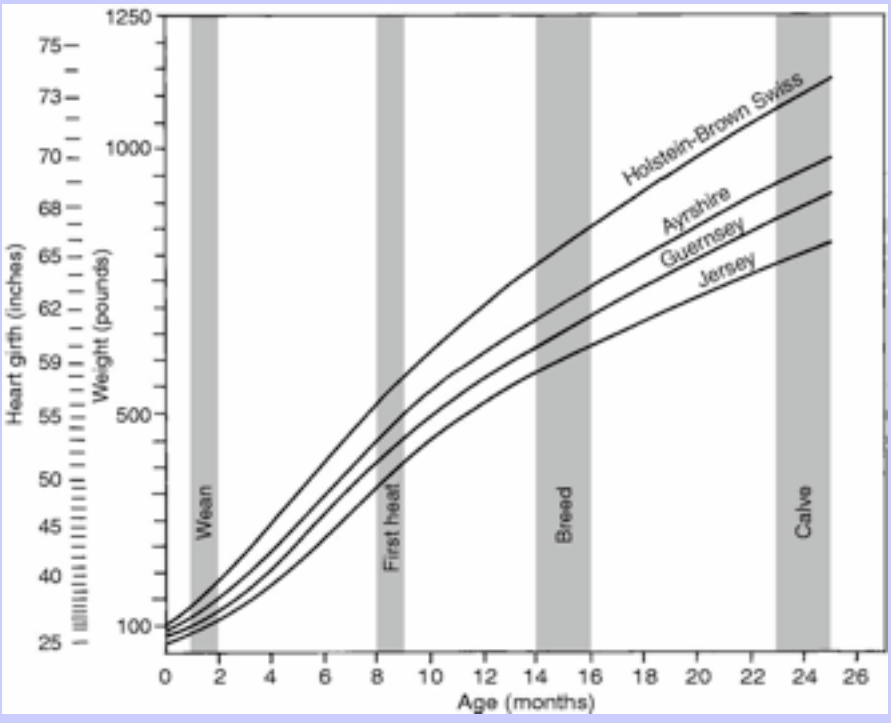

Fig. 9-4 Estimated growth curves for beef cows of various breeds. *AA*, Angus; *CC*, Charolais; *CA*, Charolais × Angus; *FA*, Holstein × Angus. Modified from Nadarajah K, Marlowe TJ, Notter DR: Growth patterns of Angus, Charolais, Charolais X Angus and Holstein X Angus cows from birth to maturity, *J Anim Sci* 59:957, 1984.

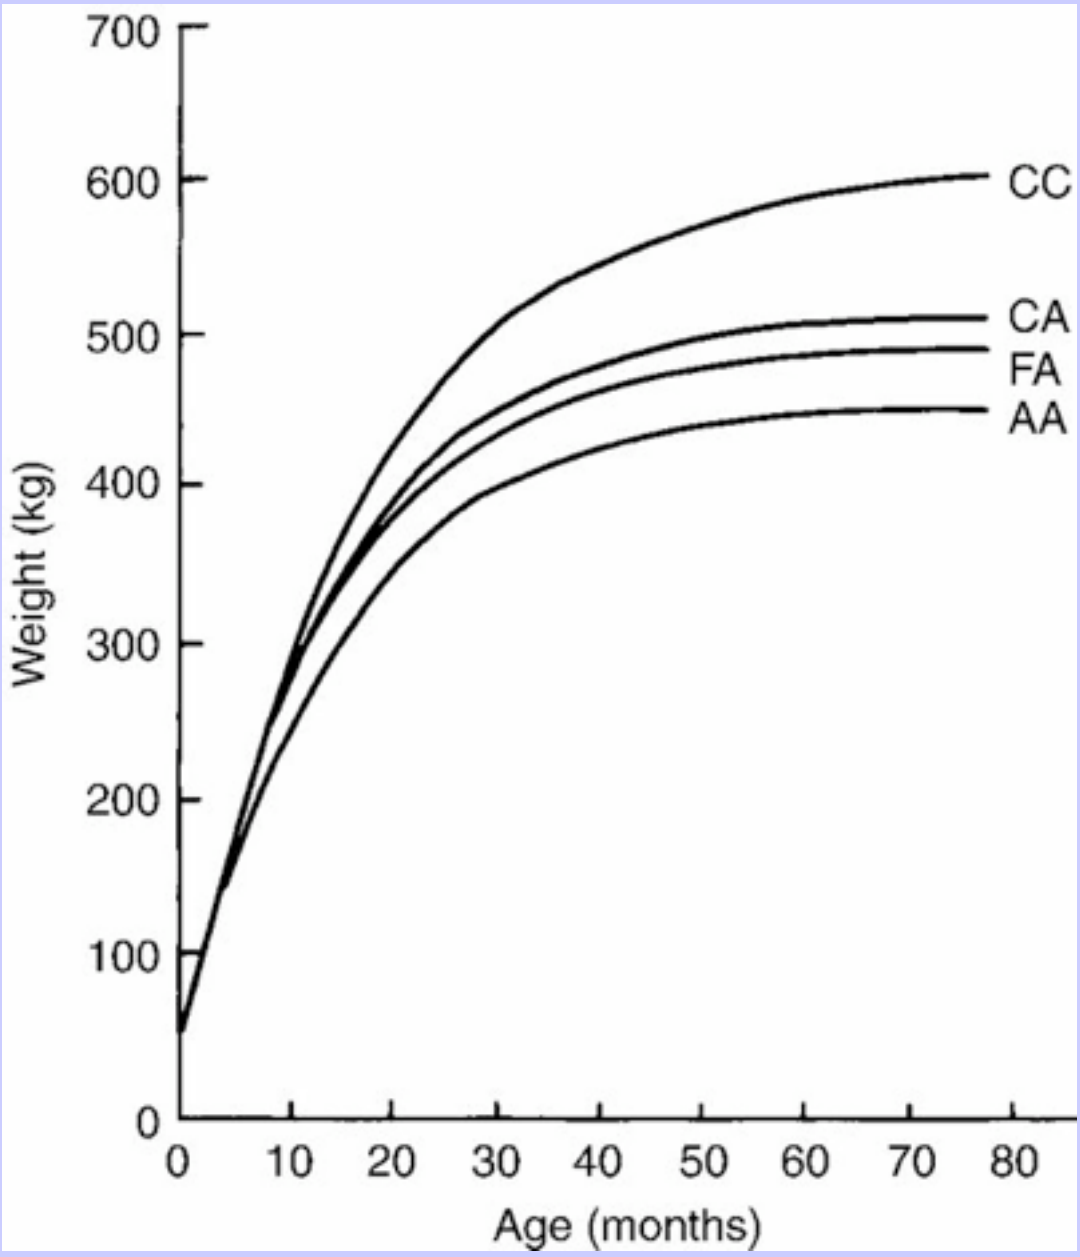

Fig. 9-5 Mean growth curves of Angus *(A)*, and Hereford *(H)*, males (♂) and females (♀). Modified from Brown JE, Brown CJ, Butts WT: A discussion of the genetic aspects of weight, mature weight and rate of maturing in Hereford and Angus cattle, *J Anim Sci* 34:525, 1972.

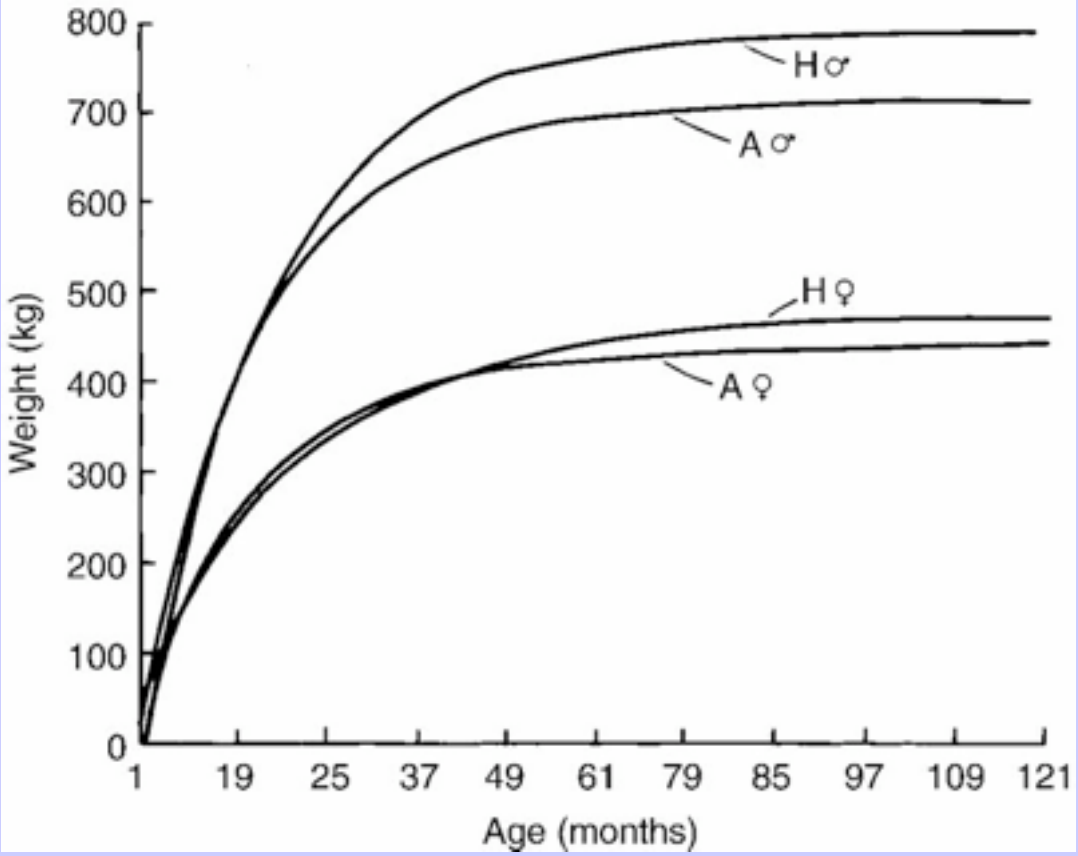


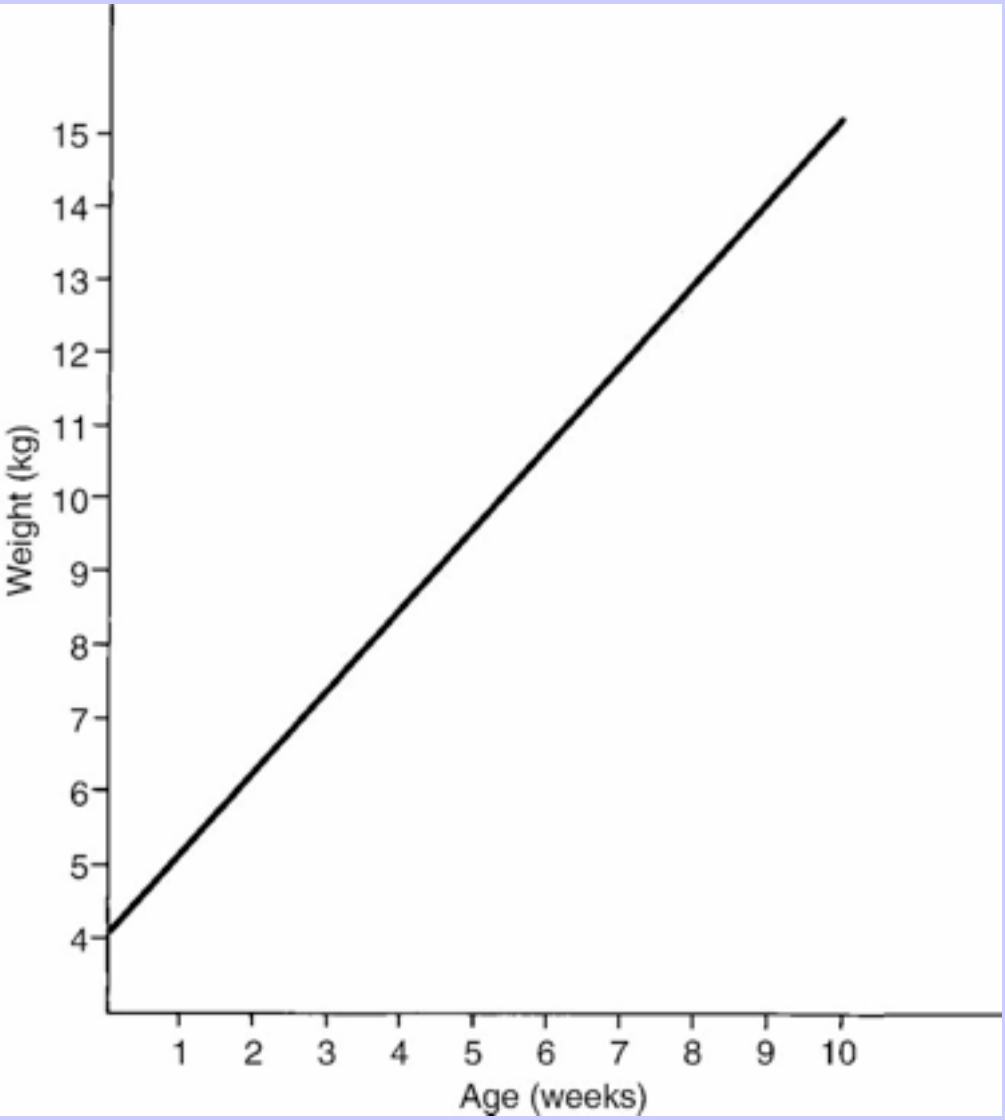
3 Examine the feces.

Perform flotation, sedimentation, and Baermann's procedures to detect patent parasitic infestation. Perform a fecal occult blood test; if the result is positive or if there is evidence of diarrhea, see the section on melena or diarrhea in Chapter 7. If diarrhea is noted in neonatal calves, refer to Chapter 20 for diagnostic and therapeutic management.

4 Perform blood analysis.

a Perform a CBC, including plasma protein and fibrinogen. Calculate the erythrocytic indices, and document and characterize the anemia if present. If a herd problem exists in a selenium-deficient region, measure the whole blood selenium concentration or glutathione peroxidase activity.

Fig. 9-6 Growth curve for young goats. Modified from Morand-Fehr P, Hervieu J, Bas P, Sauvant D: *Proc Third Int Conf Goat Prod Dis* 3:96, 1982.



b Perform a serum biochemical analysis. Serum albumin is decreased late in PCM. Albumin is normally lower in neonates (approximately 1 g/dL less) than in adults. The blood urea nitrogen (BUN) level is often low in ruminants as a result of urea recycling through saliva. Total serum calcium may be decreased with hypoalbuminemia (ionized serum calcium remains normal), anorexia, or hypocalcemic syndromes (milk fever). Serum phosphorus may be increased during severe starvation or decreased with anorexia.

Hypophosphatemia may be the result of dietary deficiency or *Brassica*, feeding, or it may be associated with copper deficiency. Measure serum (plasma) copper if a herd problem exists in a copper-deficient region (or a region with excess molybdenum or sulfate or both). Copper (serum or plasma) concentrations below 0.5 µg/mL (ppm) indicate deficiency. Liver copper levels are even more indicative of status. Serum glucose may be increased with stress or decreased or normal near death.

5 Analyze the diet and improve the feeding program.

Compare nutrient intake with the requirements for maintenance and growth of the various ruminant species (Tables 9-4 through 9-10). If the neonate is being fed a milk diet, evaluate the quality of the product and ensure that the animal's intake meets the dietary requirements (see Tables 9-4 and 9-5). Ensure that the milk replacer is mixed properly. If the ruminant is consuming a grain mix or forage, ensure that the quantity and the quality of the feed are adequate to allow sufficient intake in developed ruminants (see Table 9-1). Forage sampling instructions are listed in Box 9-3. If anorexia is present, look for more specific signs of a primary disease process. If the diet supplies adequate nutrients for maintenance and growth, consider decreased growth and decreased weight gain to be caused by a primary disease condition.

154

155

Table 9-4 Daily Energy and Protein Requirements for 50-kg Calves on a Milk Diet

	Digestible Energy Requirements	Digestible Protein Requirements
Maintenance	45–55 kcal/kg body weight	0.5 g/kg body weight
Gain	300 kcal/100 g gain in body weight*	22 g/100 g of weight gain†
0.5 kg daily gain	1500 kcal	
1 kg daily gain	3000 kcal	

* A 50-kg calf gaining 0.75 kg/day would have a daily energy requirement of 5000 kcal of digestible energy (2750 kcal maintenance + 2250 kcal/0.75 kg of gain).

† A 50-kg calf gaining 0.75 kg/day would have a daily protein requirement of 190 g of digestible protein (25 g of maintenance + 165 g of gain).

9.2 WEIGHT LOSS

The clinical problem of weight loss suggests that an individual large animal patient or a herd has lost weight over a known period of time. It may also suggest that the patient has reached a subnormal adult weight and size (see section on decreased growth and decreased weight gain, earlier). Late pregnancy, early lactation, and intense exercise are normal physiologic conditions commonly accompanied by mild to moderate weight loss. Late pregnancy can be associated with decreased body condition without actual weight loss, because weight is gained with the conceptus. During pregnancy and lactation the loss of body condition may be mild, resulting in a low normal BCS, or the loss may be severe and can threaten the health of both the dam and the neonate.

Weight loss in adult animals is most commonly associated with one or more of the following circumstances (other causes are listed in Boxes 9-5 and 9-6):

- Anorexia
- Increased nutrient demands
- PCM
- Micronutrient deficiencies
- Parasitism

Anorexia usually occurs secondary to a primary disease. Increased nutrient requirements are associated with normal physiologic conditions (e.g., pregnancy, lactation, exercise, cold weather) and with pathologic processes (e.g., sepsis, trauma, parasitism, burns). Mild to severe PCM is often associated with inadequate feed quality (see Table 9-1) or quantity but can also be caused by increased energy requirements resulting from adverse environmental conditions. Weight loss can also occur with a deficiency of essential micronutrients such as copper, cobalt (vitamin B_{12}), or vitamin A. Parasitism should always be on the differential list in an animal that has lost weight.

156

159

9.2.1

Box 9-5 Causes of Weight Loss in Horses

9.2.1.1

COMMON CAUSES

Protein-calorie malnutrition (PCM)

Parasitism

Dental, jaw abnormalities

Sand enteropathy

Chronic colonic impaction

Gastric ulcers

Right dorsal colitis

Peritonitis

Internal abdominal abscess

Streptococcus equi, (lymph node abscessation, pulmonary or mesenteric abscessation)

Pneumonia (bacterial, viral)

Pleuritis, pleuropneumonia, pulmonary abscessation

Chronic obstructive pulmonary disease

Chronic renal failure

Acute renal failure

Pituitary pars intermedia dysfunction

Neoplasia (alimentary tract)

9.2.1.2 LESS COMMON CAUSES

Guttural pouch infection

Otitis media, interna

Paranasal sinus infection

Oral foreign body

Vesicular stomatitis

Esophageal abnormalities (esophagitis, diverticula)

Gastric squamous cell carcinoma

Duodenal ulcers

Gastric impaction

Lymphocytic-plasmacyte enterocolitis

Eosinophilic enterocolitis

Multisystemic eosinophilic epitheliotropic disease

Granulomatous enteritis

Proliferative enteropathy

Idiopathic diarrhea

Toxic hepatopathy

Chronic hepatitis

Cholelithiasis

Pyrrolizidine alkaloid hepatotoxicity

Amyloidosis

Urolithiasis

Renal tubular acidosis

Glomerulonephritis

Pyelonephritis

Renal neoplasia

Urinary bladder neoplasia

Osteomyelitis

Infectious arthritis

Atrial fibrillation

Cardiac or great vessel anomalies

Congestive heart failure

Endocarditis, pericarditis

Splenic rupture, abscess

Lymphoma, lymphosarcoma

Malignant melanoma

Granulosa cell tumor

Purpura hemorrhagica

Autoimmune anemia or thrombocytopenia

Cauda equina neuritis

Equine motor neuron disease

Nocardiosis

Coccidioidomycosis

Cryptococcosis

Agammaglobulinemia

Anhidrosis

Giardiasis

Aflatoxicosis

Equine adenovirus

Equine viral arteritis

Equine infectious anemia

9.2.1.3 UNCOMMON CAUSES

Rabies

Nigropallidal encephalomalacia

Botulism

Nutritional myodegeneration

Rectus capitus ventralis muscle rupture

Skeletal or vertebral neoplasia

Spinal abscessation

Micronema deletrix, infection of the central nervous system

Rhodococcus equi, infection

Tuberculosis

Pleural mesothelioma

Pneumocystis carinii, pneumonia

Pulmonary aspergillosis

Micropolyspora faeni, hypersensitivity pneumonitis

Testicular neoplasia

Mammary carcinoma

Ovarian adenoma

Pancreatic neoplasia

Malignant mesothelioma

Pulmonary neoplasia

Strongylus vulgaris, thromboembolism

Portal vein shunt

Liver fluke

Theiler's disease

Basophilic enterocolitis

Ileal hypertrophy

Myeloproliferative disease

Pyloric stenosis

Colonic fistula

Prognathia, brachygnathia

Aortic aneurysm

Enzootic cystitis

Polycystic disease

Pheochromocytoma

Hyperparathyroidism

Diabetes mellitus

Systemic granulomatous inflammation

Seborrhea

Bullous pemphigoid

Panniculitis

Lupus erythematosus

Pemphigus foliaceous

Eosinophilic dermatitis

Horsefly-deerfly infestation

Wound myiasis

Steatitis

Goiter

Erythrocytosis

Histoplasmosis

Phycomycosis

Fungal granuloma

9.2.3

Mechanisms of Weight Loss

Anorexia is the loss of appetite or lack of desire for food; it may be complete or partial. It is a primary mechanism for weight loss of short or intermediate duration. Weight loss results from decreased nutrient intake. When partial anorexia occurs over a long period, the weight loss may be subtle and go unrecognized. Acute, complete anorexia results in more dramatic weight loss.

In domestic species, anorexia is usually associated with a primary disease condition and is regulated by cytokines, including interleukin (IL)-1 and tumor necrosis factor alpha (TNF-α), released during an inflammatory response. Resolution of the primary disease process usually results in a return to voluntary food consumption. Anorexia must be differentiated from dysphagia by observation. The distinction between the conditions that cause anorexia and those that control hunger and satiety is not clear; however, many diseases that cause anorexia also result in dehydration, electrolyte imbalances, and/or acid-base disorders.

159

160

In addition to causing anorexia, many disease processes cause an increase in the nutrient requirements for basal metabolism. Nutrient requirements for maintenance, growth, pregnancy, lactation, and exercise have been well defined for many large animal species. Nutrient requirements in disease have not been adequately evaluated in large animals, and most information is currently extrapolated from humans, laboratory animals, and small animal species. In human patients, published estimates indicate that requirements for energy and protein increase

approximately 10% after elective surgery, 20% with fractures, 30% to 60% with severe infection or sepsis, 40% with peritonitis, and 50% to 110% with major burns.[7,8] In humans, the resting energy expenditure is estimated to increase by 14% for each degree Celsius increase in body temperature.[9] Extrapolation of these data directly to equine and ruminant patients is probably not possible; however, the figures do indicate the degree of change in nutrient requirements as a result of disease. The stress of many disease processes results in an increase in serum cortisol and in glucagon. The decreased insulin/glucagon ratio alters the production of glucose and results in hyperglycemia because of enhanced hepatic gluconeogenesis. An increase in sympathetic activity appears to regulate fat oxidation, the increased release of fatty acids from cellular lipid stores, and the development of hypertriglyceridemia in many patients with sepsis. Protein degradation and a negative nitrogen balance are also hallmarks of the acute response to infection. Weight loss resulting from protein and lipid catabolism is often observed in large animal patients with sepsis, owing to altered metabolic activity and nutrient requirements.

In conditions such as burns, peritonitis, pleuritis, colitis, and granulomatous bowel disease, nutrients (particularly proteins) are lost. In many disease conditions, concurrent anorexia and increased nutrient requirements greatly increase the risk of PCM and weight loss. Certain conditions, such as Johne's disease in ruminants and granulomatous enteritis in horses, are also associated with a malabsorption or malassimilation syndrome. In these types of diseases, nutrients are not efficiently digested and absorbed; anorexia may be absent, and dietary intake may appear normal, but weight loss still occurs.

PCM continues to be a persistent problem in domestic animals. Inadequate ingestion of energy and protein obviously results in weight loss, but PCM and associated weight loss can occur through several other mechanisms. The most direct cause is that the animal receives an inadequate volume of feed to meet their dietary requirements. This can occur as frank underfeeding of all animals or as a consequence of inadequate feeding facilities that create competition among animals for available feed. The latter circumstance occurs most dramatically when animals of varying ages are mixed; the younger animals with the highest requirements are often pushed away by older, dominant individuals.

The quality of the diet, particularly dietary forages such as hay and pasture, is an important factor in the development of PCM and total nutrient intake. Table 9-1 lists guidelines for estimating the maximum daily intake by cattle. It is evident that as forage quality (digestibility) decreases, maximum daily intake decreases because poor-quality feed must remain in the rumen for an increased period of time before it is sufficiently digested to allow passage through the reticuloomasal orifice. Maximum dry matter intake (DMI) as a percentage of body weight is somewhat higher in small ruminants than in cattle. However, the energy requirement per kilogram of body weight is higher in small ruminants than in cattle. Similar estimates for maximum DMI in horses related to forage quality are not available. Horses do not have a pregastric fermentation organ (rumen) and can ingest slightly more of the same quality forage than cattle. Low-quality forages are often the cause of PCM, even when an unlimited quantity is available. The best way to determine the nutrient content of forage, grain, and pelleted feeds is to have the feed analyzed by a forage laboratory. Feed analysis instructions are provided in Box 9-3. Feed tag labels or forage databases can be referenced if a forage analysis is not performed.

Environmental factors can have a major influence on nutrient requirements and can increase the subsequent risk for PCM and weight loss. The most important environmental factor is the ambient temperature. Nutrient requirements for maintenance change with a decreasing ambient temperature as follows:

- *Adult horses:*, Estimated increase in digestible energy (DE) requirements by 2.5% for every degree Celsius below the lower critical temperature (LCT). The LCT for adult horses ranges from 5° C to −15° C, depending on the horse?s adaptation to the environment. In cold temperatures, when the hair coat is wet, the maintenance DE requirement may be increased by as much as 50%.[10]

- *Beef cattle:*, 1% increase in maintenance energy requirements (total digestible nutrients [TDN], net energy of maintenance [NE_m], digestible energy [DE], and metabolizable energy [ME]) for each 1° C drop below 20° C (68° F).
- *Dairy cattle (lactating):*, 25% increase in energy requirements (TDN, net energy of lactation [NE_L]) as ambient temperature drops from 20° C (68° F) to −10° C (14° F).
- *Sheep with 10-cm wool:*, 1% increase in energy requirements (TDN, ME, DE) for each 1° C drop below lower critical temperature (approximately −10° C).

There are also additive effects of wind and rain that increase energy requirements in large animal species. As nutrient requirements increase, the dietary intake must also increase to prevent weight loss associated with PCM. Horses in inclement weather may not be able to consume enough forage to meet their increased energy requirements, and for these animals, dietary fat and limited grain supplementation may be required.

Deficiencies of micronutrients (trace minerals, B vitamins) often result in inefficiencies in basic biochemical pathways. These inefficiencies, if marked, can be associated with weight loss. Genetic errors in metabolism can cause similar disturbances, but these usually manifest as decreased growth and even death in young animals.

Parasitism is a common cause of weight loss in adult domestic animals. The mechanisms by which parasite infestation can result in weight loss include a loss of body fluid and tissues resulting in increased nutrient requirements, competition for nutrients in the gastrointestinal tract, malassimilation and malabsorption, inflammation resulting in increased nutrient requirements, micronutrient deficiencies, and organ or vascular damage from migrating parasite larvae. Anorexia may also develop in the advanced stages of severe parasitism.

9.2.4 Approach to the Diagnosis and Management of Weight Loss in Adult Horses

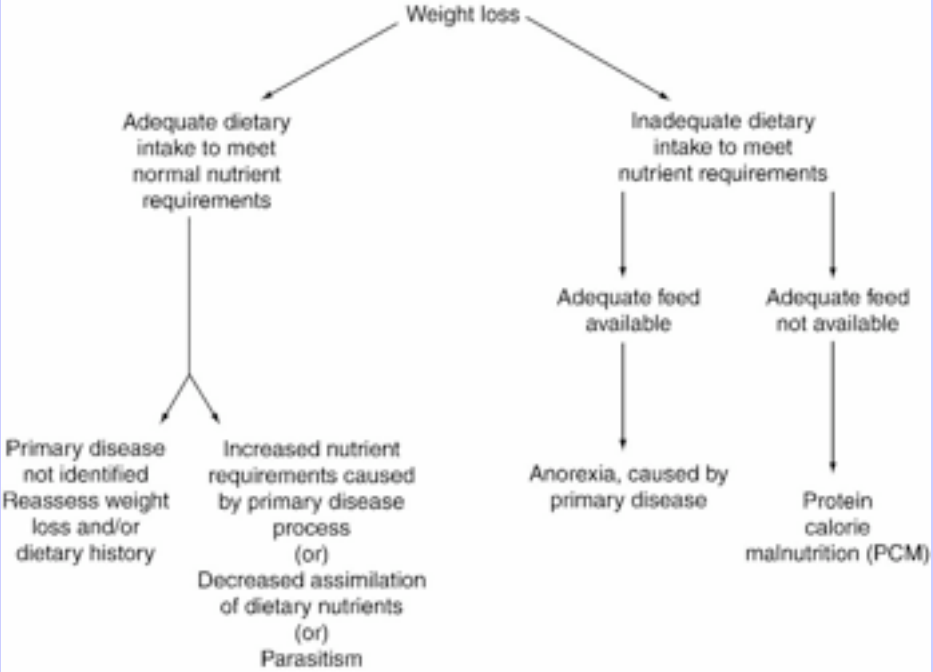
Use the flow sheet in Fig. 9-7 to aid in decision making.

1 Take a general history and a diet history.

a General history

i Is the weight loss affecting one animal, or many animals? If many horses are affected, what is the age range of the affected animals? How long has the caretaker noticed weight loss in the horse? How much weight has been lost? Is this an estimate of weight loss, or have the horse(s) been monitored on a scale or with a weight tape? What is the change in BCS of the horse(s)? Has the diet been changed to manage the weight loss? Weight loss is often suspected but not documented in the initial complaint or history. Acute weight loss of 5% to 10% is significant. Quantitation of weight loss and BCS changes is important.

Fig. 9-7 Flow sheet for classifying conditions associated with weight loss.



If a weight tape will not fit around the girth of the horse, or if the horse has a BCS of 1 to 3, a body weight estimate is made using measurements of the length and girth of the horse.[11–12] Length is measured from the tuber ischium to the point of the shoulder, and girth is measured at the withers, behind the elbows, at the end of expiration.

$$\text{Body weight (kg)} = \frac{\text{Chest girth (cm)}^2 \times \text{Length (cm)}}{11877}$$

The weight of miniature horses should be obtained using a small animal clinic scale. If a scale is not available to weigh a miniature horse, then the following equation can be used to estimate the weight of the miniature horse.[13]

$$\text{Body weight (kg)} = \frac{(3.7 \times \text{Chest girth in cm}) + (2 \times \text{Length in cm}) - 348.5}{2.2}$$

ii Is there any past or current clinical disease in the horse or herd? If so, when was the disease first diagnosed? How many animals were affected? What type of treatment was administered? Was the diet changed during this period of time? Question the caretaker closely about any clinical signs of diarrhea, coughing, dysphagia or polyuria. What is the deworming history of the horse and herd? Has the deworming protocol been changed lately?

b Diet history

i Obtain an *accurate*, dietary history including the type and amount of feed offered (in pounds, ounces) and the amount of feed refused by the horse(s). It is essential that feeds are weighed accurately. Nutrient requirements of adult ponies and horses are listed in Table 9-11. For how long does the horse have access to pasture? What type of grass is available in the pasture? Is the pasture overgrazed? Are any diet supplements fed to the horse? If so, what amount is fed? Does the horse have access to a salt or trace mineral block? How long has this diet been fed? Have there been any changes in the forage offered to the animals? Forage quality is often not consistent between hay shipments. Has a forage analysis been performed on the pasture or hay? If yes, obtain a copy of the analysis for the patient record. Inspect the pasture and all feeds for gross quality, evidence of spoilage, abnormal color or odor, presence of weeds and mold, and quantity of feed the owner has at the facility.

ii How are the horses fed? What type of feeder is used? Are mats placed under the feeders to reduce sand and dirt ingestion? Is there competition among the horses for food? Are there any toxic substances in the horse's environment? What is the water source for the horses? Is the water clean?

2 Perform a physical examination.

a Observe the horse while it is eating forage. Can the horse prehend, masticate, and swallow food normally? Is the horse dysphagic? Does the horse have a good appetite? Is the horse hungry? Are there any signs of neurologic disease?

b Examine the patient closely to identify signs of concurrent disease (e.g., pyrexia, diarrhea, melena, dysphagia, abnormal dentition, icterus, nasal discharge, cough, dyspnea, tachycardia, cardiac murmur, dysuria).

c What are the horse's body weight (scale or weight tape) and BCS (see Table 9-21)?

3 Examine the feces.

What is the consistency of the feces? If the horse has evidence of diarrhea, review the section on diarrhea in Chapter 7. How long are the fibers in the feces? Perform a glove test. Is there evidence of sand in the feces? Horses can have a significant volume of sand in the large intestine while having negative fecal sand test results. Perform a fecal egg count. An enzyme-linked immunosorbent assay (ELISA) may be useful in diagnosing a tapeworm infection. Follow the parasite control program in Chapter 49 if the horse has evidence of fecal parasites or if a parasite infection is suspected despite a negative fecal egg count. Perform a fecal occult blood test; if the result is positive, see the section on melena in Chapter 7.

Table 9-11 Daily Nutrient Requirements of Ponies and Horses of Mature Body Weight

Category	Digestible Energy (Mcal)	Crude Protein (g)	Calcium (g)	Phosphorus (g)
MATURE PONIES, 200 KG (440 LB) OF MATURE BODY WEIGHT				
Maintenance, average activity	6.7	252	8	5.6
Mares, last 90 days of gestation	7.7–8.6	319–357	14.4	10.5
Lactation, first 3 months	12.7–12.2	614–587	23.6–22.4	15.3–14.4
MATURE HORSES, 400 KG (880 LB) OF MATURE BODY WEIGHT				
Maintenance, average activity	13.3	504	16	11.2
Mares, last 90 days of gestation	15.4–17.1	637–714	28.8	21
Lactation, first 3 months	25.4–24.5	1228–1174	47.3–44.7	30.6–28.8
MATURE HORSES, 500 KG (1100 LB) OF MATURE BODY WEIGHT				
Maintenance, average activity	16.7	630	20	14
Mares, last 90 days of gestation	19.2–21.4	797–893	36	26.3
Lactation, first 3 months	31.7–30.6	1535–1468	59.1–55.9	38.3–36
MATURE HORSES, 600 KG (1320 LB) OF MATURE BODY WEIGHT				
Maintenance, average activity	20	756	24	16.8
Mares, last 90 days of gestation	23.1–25.7	956–1072	43.2	31.5
Lactation, first 3 months	38.1–36.7	1842–1761	70.9–67.1	45.9–43.2
MATURE HORSES, 900 KG (1980 LB) OF MATURE BODY WEIGHT				
Maintenance, average activity	30	1134	36	25.2
Mares, last 90 days of gestation	34.6–38.5	1434–1607	64.8	47.3

Lactation, first 3 months	54.4–52.4	2763–2642	106.4–100.6	68.9–64.9

Modified from National Research Council (NRC): *Nutrient requirements of horses*, Washington, DC, 2007, National Academies Press.

4 Perform blood analyses.

a Perform a CBC, including plasma protein and fibrinogen. Examine the results closely for indication of an inflammatory process (e.g., leukocytosis, neutrophilia, leukopenia, neutropenia, hyperfibrinogenemia, decreased plasma protein/fibrinogen ratio [below 10]). Calculate the erythrocytic indices, and characterize anemia, if present.

b Perform a serum biochemical analysis. The serum albumin half-life is approximately 19 days in horses. Hypoalbuminemia may be associated with colitis, internal abscessation, PCM, liver disease, renal disease, and granulomatous bowel disease, among other conditions. Albumin is often within normal limits in PCM until the patient is near death. Globulin (particularly γ-globulins) may be increased with inflammation, and the albumin/globulin ratio may be decreased. The glucose concentration is usually normal or elevated as a result of stress and may also be elevated in horses with pituitary pars intermedia dysfunction (PPID) and equine metabolic syndrome. Hyperlipidemia (serum triglyceride between 100 and 500 mg/dL) is commonly associated with early anorexia and can be present in horses with PPID. Hyperlipemia (serum triglyceride above 500 mg/dL) is a serious condition associated with prolonged anorexia and hepatic lipidosis and is often found in miniature horses, ponies, and donkeys under severe physiologic stress (PCM and lactation). Unconjugated bilirubin levels can rise to 6 or 7 mg/dL with anorexia or decreased food intake. An elevated γ-glutamyltransferase (GGT) (above 25 IU/L) may indicate hepatic disease. Horses with PCM may have a low serum urea nitrogen if the protein malnutrition is prolonged and severe.

5 Analyze the diet and improve the feeding program.

a Determine if the energy, protein, mineral, and vitamin content of the diet meets the nutrient requirements of the horse at their current metabolic state and activity level (see Table 9-11). Include pertinent environmental and management factors in the nutrient requirement calculations. The quality of the feeds should be assessed.

i Forage

The most accurate way to determine the nutrient content of forage or pasture is with an analysis. See Box 9-3 for instructions on how to sample feeds for analysis. Contact a university extension service for forage analysis. If the client does not purchase a large volume of hay, or if analysis cannot be performed, forage tables from the Nutrient Requirement Council reference books (www.nap.edu), or nutrient tables from the Equi-Analytical Laboratories forage laboratory database (www.equi-analytical.com) can be used to estimate the concentration of different nutrients in common forages and supplemental feeds.

ii Commercial Feeds

The guaranteed analysis on feed tag labels provides the nutrient content of certain ingredients. Contact commercial feed companies for the energy content of their products.

b If the horse has a dietary deficiency, the problem should be corrected by a change in the diet or through appropriate supplementation. Contact an equine clinical nutritionist for guidance on ration formulation.

c If the dietary history indicates that adequate nutrients for maintenance and performance have been steadily consumed, continue to search for another cause of the weight loss.

6 Perform ancillary diagnostic tests.

If the weight loss is not caused by inadequate or poor-quality feed, additional diagnostic tests should be performed. Possible tests include but are not limited to ultrasound, gastric endoscopy, radiographs, serum or whole blood trace mineral analysis, serum insulin concentration, carbohydrate absorption tests (oral D-glucose, D-xylose [see Chapter 32]), and appropriate organ biopsy.

Table 9-12 Daily Nutrient Requirements for Dairy Cattle

Body Weight						
(kg)	(lb)	NE_L (Mcal)	Total Digestible Nutrients (kg)	Crude Protein (g)	Calcium (g)	Phosphorus (g)
MAINTENANCE OF MATURE LACTATING COWS						
400	880	7.16	3.15	373	15	13
500	1100	8.46	3.72	432	18	15
600	1320	9.7	4.27	489	21	17

Modified from National Research Council (NRC): *Nutrient requirements of dairy cattle*, Washington, DC, 2001, National Academy of Sciences, NRC.NE_L, Net energy of lactation.

The energy requirement for milk production when only the butterfat content of the milk is known by the following formula:

NE_L (Mcal/kg milk) + 0.360 + (0.0969[fat%]).

9.2.5

Approach to the Diagnosis and Management of Weight Loss in Adult Ruminants

1 Take a general history and a diet history.

a General history

Question the caretaker closely about any clinical signs that might indicate a primary disease (e.g., diarrhea, coughing, dysphagia, polyuria, depression, agalactia). Note if body condition is less than desired. Quantitate the weight loss or BCS if possible. Acute weight loss of 5% to 10% is quite significant. Carefully note the production level of the animal or herd (e.g., pregnancy [single, twins, triplets], lactation [level of milk production]). Evaluate the parasite control program. Does the herd have a history of chronic or recurrent disease (Johne's disease, bovine virus diarrhea, ruminal lactic acidosis, laminitis, mastitis, pneumonia)?

b Diet history

Obtain an *accurate*, dietary history, particularly when signs of a primary disease are absent. Inspect all forages, concentrates, and feed additives for quality, signs of spoilage, abnormal color or odor, and quantity on hand. Be sure the feeding system allows for adequate consumption by all animals and that competition for feedstuffs does not occur. Check to see if the feeding program was changed before the onset of observed weight loss or loss of body condition. The history should include the *weight*, of each feedstuff and supplement fed and consumed per day. The maximum DMI can be estimated according to feed quality for cattle (see Table 9-1). Determine or estimate the nutrient analysis of the feedstuffs being fed. Examine the environment for possible toxic plants or substances.

2 Perform a physical examination.

Examine patients carefully for signs of concurrent disease (e.g., diarrhea, decreased ruminal motility, pyrexia, dysphagia, abnormal dentition, melena, icterus, mastitis, metritis, dyspnea, tachycardia). Is the patient hungry? Weigh the patient (or use a heart-girth measurement) and note the BCS (see Tables 9-18 through 9-20). Observe the patient for signs of muscle wasting and the presence or absence of subcutaneous fat. Test the milk with nitroprusside powder (a positive reaction indicates an acetoacetate concentrate above 5 mg/dL and is diagnostic of ketonlactia and ketonemia), or measure the ketone concentration in the urine. Measure the ruminal pH (pH above 7 is indicative of anorexia). Examine the skin for evidence of lice or keds.

3 Examine the feces.

Perform flotation, sedimentation, and Baermann's procedures to detect patent parasitic infestations. If the feces test positive for occult blood or are very dark, see the section on melena in Chapter 7. If there is evidence of or apparent diarrhea, see the section on diarrhea in Chapter 7.

4 Perform blood analysis.

a Perform a CBC, including plasma protein and fibrinogen. Interpret for evidence of inflammation. Calculate the erythrocytic indices, and characterize the anemia if present. Analyze for blood selenium concentration or glutathione peroxidase activity if a herd problem of weight loss exists in a selenium-deficient region.

b Perform a serum chemistry analysis. The serum albumin half-life is approximately 16½ days in cattle and 14 days in sheep and goats. Hypoalbuminemia is associated with internal abscessation, PCM, liver disease, renal disease, and Johne's disease, among other conditions. In the first two of these conditions, albumin is often normal until the patient is near death, whereas with protein-losing renal or gastrointestinal disease or with failure to make albumin in severe hepatic disease,

hypoalbuminemia is often seen by the time noticeable weight loss occurs. Globulins, particularly γ-globulins, may be increased with inflammation, and the albumin/globulin ratio may be decreased. The serum glucose concentration is usually not helpful in determining the cause or causes of weight loss. An elevated serum GGT (above 25 IU/L) may indicate hepatic disease or, in rare cases, pancreatic disease. Serum BUN is often low with PCM in ruminants because of salivary urea recycling. Serum (total) calcium may be decreased with hypoalbuminemia, anorexia, or hypocalcemic syndromes. Serum phosphorus may be increased during severe starvation or Johne's disease or decreased with anorexia. The serum (plasma) copper concentration may be decreased if a herd problem of copper deficiency exists. Weight loss is particularly associated with copper deficiency when diarrhea is present in a region known to be copper deficient or in a region with excess dietary molybdenum or sulfates or both. A low serum copper concentration (below 0.5 μg/mL or ppm) indicates deficiency. Ketonlactia (above 5 mg/dL), indicated by a positive reaction (blue or purple) of milk with nitroprusside, may be associated with anorexia in ketosis or other conditions. Plasma β-hydroxybutyrate (BHB) concentrations have been reported to be a useful tool in diagnosing *inadequate caloric intake*, in pregnant sheep.[14] Plasma BHB concentrations should be less than 0.8 mmol/L in pregnant ewes consuming adequate energy.[14]

5 Analyze the diet and improve the feeding program.

Is the feed quantity and quality adequate to allow sufficient intake of nutrients (see Table 9-1)? Compare the nutrient intake from the diet with the requirements for the appropriate species (Tables 9-12 through 9-17). Consider any important environmental and management factors in the daily nutrient requirements. Review nutrient analysis profiles on the feeds and total mixed ration (TMR) ingredients. Is the TMR mixed properly? Are grain rations mixed properly? Is too much grain being fed to the animal or herd? Analyze the pasture, forage, or concentrate rations (see Box 9-3). Make appropriate recommendations to optimize the ration. Determine if the patient or patients have a normal appetite. Is anorexia present? If the dietary history and analysis indicate that adequate nutrients have been steadily consumed, the search for a primary cause for the weight loss should be resumed.

163

164

6 Perform ancillary diagnostic tests.

a If the weight loss is not related to the diet, additional diagnostic tests should be performed on the animal or on a number of animals in the herd. Possible tests include but are not limited to trace mineral analyses, ultrasound, and appropriate organ biopsy.

b Pathologic findings of affected ruminants often provide evidence of the effects of a systemic disease or of chronic malnutrition. Ruminants with PCM exhibit serous atrophy of fat in the coronary grooves of the heart and bone marrow at necropsy. Subcutaneous, abdominal, and perirenal fat are not present.

9.3 OBESITY

9.3.1 Mechanisms of Obesity

Obesity is a common problem in domestic species. The prevalence of obesity is increasing in the domestic horse population, and obesity is a significant problem in many ruminant species raised as companion animals. Obese patients (especially ruminants) are at particular risk for reproductive failure or metabolic disease late in pregnancy or during lactation. The risk of obstructive urolithiasis increases in overweight goats and sheep. In

164

horses, obesity may be related to a variety of diseases including equine metabolic syndrome, laminitis, and colic associated with strangulating lipomas. Obese horses and ponies that are rapidly losing weight or that are anorexic are particularly susceptible to hyperlipidemia and hyperlipemia.

Table 9-14 Daily Nutrient Requirements for Mature Beef Cows

Reproductive Status	Daily Gain (kg)	Digestible Energy (Mcal/day)	Crude Protein (kg)	Calcium (g)	Phosphorus (g)

90	198	11.28	2554	476	19	13.3

Modified from National Research Council (NRC): *Nutrient requirements of goats*, Washington, DC, 1981, National Academy of Sciences, NRC.

The mechanism of obesity is invariably a prolonged intake of total dietary energy above that needed for maintenance and either production or exercise. Obesity occurs most commonly in stabled horses fed high-energy feeds such as grain or high-fat supplemental feeds and in horses and ponies on lush pasture. Even horses that are fed a forage diet but have limited access to exercise may gain weight if they consume an excess amount of energy for their body size. Purebred or pet sheep and goats (particularly wethers) tend to be overfed. In dairy cattle, obesity occurs when cattle are fed well above requirements for maintenance and milk production. Poor reproductive performance is often associated with the initiation of obesity and is also a common sequela to obesity. Feeding for high milk production for lengthy periods in production groups predisposes infertile cows to become fat cows. Dry cows with access to high-energy diets are also predisposed to fat cow syndrome. The systemic complications associated with fat cow syndrome (fatty liver), and its diagnosis and treatment, are described in Chapter 33.

9.3.2 Diagnosis of Obesity in Horses and Ruminants

Diagnosis is obvious; it is made by physical examination. Overweight and obese animals have an elevated BCS (7 to 9/9 for horses; 8 to 9/9 for beef cattle; 4 to 5/5 for dairy cattle, sheep, and goats). Palpation of the back, gluteal area, and ribs should be included in the physical examination of sheep and camelids with long wool or fiber and of horses with a long winter hair coat so that a BCS can be accurately assigned. In some animals, external signs of fat deposition may be subtle. In these cases, ultrasonography can be used to identify the extent of deposition of intraabdominal fat in horses and of back fat in cattle. Clinical descriptions of obesity provided

by the body condition scoring system are straightforward (Tables 9-18 to 9-21) and require minimal interpretation.

In some animals, obesity can be mistaken for the normal physiologic condition of pregnancy. In other cases, obesity could be mistaken for a distended abdomen from acute pathologic disease conditions including uroabdomen and peritonitis. A full physical examination should always be performed on a large animal patient before a weight loss ration is fed.

Table 9-18 Body Conditioning Scoring System for Beef Cattle

Group	Score	Definition
	1	Emaciated (Body fat = 3.77%)
		Cow is extremely emaciated with no detectable fat over spinous processes, transverse processes, hipbones, or ribs. Tailhead and ribs project quite prominently.
	2	Poor (Body fat = 7.54%)
Thin condition		Cow still appears somewhat emaciated, but tailhead and ribs are less prominent. Individual spinous processes are still rather sharp to the touch, but some tissue exists along spine.
	3	Thin (Body fat = 11.3%)
		Ribs are still individually identifiable but not quite as sharp to the touch. There is obvious palpable fat along spine and over tailhead and some tissue cover over dorsal part of ribs.
	4	Borderline (Body fat = 15.07%)
Borderline condition		Individual ribs are no longer visually obvious. Spinous processes can be identified individually on palpation but feel rounded rather than sharp. There is some fat cover over ribs, transverse processes, and hipbones.
	5	Moderate (Body fat = 18.89%)
		Cow has generally good overall appearance. On palpation, fat cover over ribs feels spongy, and areas on either side of tailhead now have palpable fat cover.
	6	High moderate (Body fat = 22.61%)
Optimum moderate condition		Firm pressure must be applied to feel spinous processes. High degree of fat cover is palpable over ribs and around tailhead.
	7	Good (Body fat = 26.38%)
		Cow appears fleshy and obviously carries considerable fat. There is a very spongy fat cover over ribs and over and around tailhead. “Rounds” or “pones” of fat are beginning to be obvious. There is some fat around vulva and in crotch.

	8	Fat (Body fat = 30.15%) Cow is very fleshy and overconditioned. Spinous processes are almost impossible to palpate. There are large fat deposits over ribs, around tailhead, and below vulva. “Rounds” or “pones” of fat are obvious.
Fat condition	9	Extremely fat (Body fat = 33.91%) Cow is obviously extremely wasty and patchy and looks blocky. Tailhead and hips are burled in fatty tissue, and “rounds” or “pones” of fat protrude. Bone structure is no longer visible and barely palpable. Animal's mobility may even be impaired by large fatty deposits.

From Spitzer JC: Influences of nutrition on reproduction in beef cattle. In Morrow DA, ed: *Current therapy in theriogenology*, Philadelphia, 1986, Saunders; and modified from National Research Council (NRC): *Nutrient requirements of beef cattle, 7th revised edition*, Washington, DC, 1996, National Academy of Sciences, NRC.

Table 9-19 Body Conditioning Scoring System for Dairy Cattle

Score	Description
1	Individual spinous processes have limited flesh covering and are prominent; the ends are sharp to the touch, and together the processes form a definite overhanging shelf effect to the loin region. Individual vertebrae of the chine, loin, and rump regions are prominent and distinct. Hooks and pin bones are sharp with negligible flesh covering, and severe depressions between hooks and pin bones are noted. The area below the tailhead and between the pin bones is severely depressed, causing the bone structure of the area to appear extremely sharp. (Body fat = 3.77%)
2	Individual spinous processes are visually discernible but not prominent. The ends of processes are sharp to the touch, although they have greater flesh covering, and the processes do not have a distinct overhanging shelf effect. Individual vertebrae of chine, loin, and rump regions are not visually distinct but are readily distinguishable by palpation. Hooks and pin bones are prominent, but the depression between them is less severe. The area below the tailhead and between the pin bones is depressed, but the bone structure is not devoid of flesh covering. (Body fat = 11.3%)
3	Spinous processes are discernible by applying slight pressure. Together the processes appear smooth, and the overhanging shelf effect is not noticeable. Vertebrae of the chine, loin, and rump regions appear as rounded ridges, and hooks and pin bones are rounded and smooth. The area between the pin bones and around the tailhead appears smooth, with no sign of fat deposition. (Body fat = 18.84%)
4	Individual spinous processes can be distinguished only by firm palpation, and together the processes appear flat or rounded with no overhanging shelf effect. The ridge formed by the vertebral column of the chine region is rounded and smooth, but loin and rump regions appear flat. Hooks are rounded, and the span between the hooks is flat. The area around the tailhead and pin bones is rounded, with evidence of subcutaneous fat deposition. (Body fat = 26.38%)
5	Bone structure of the vertebral column, spinous processes, hooks, and pin bones is not visually apparent, and evidence of subcutaneous fat deposition is prominent. The tailhead appears to be buried in fatty tissue. (Body fat = 33.9%)

From Wildman EE et al: *J Dairy Sci*, 65:495–501, 1982; and modified from National Research Council (NRC): *Nutrient requirements of dairy cattle*, Washington, DC, 2001, National Academy of Sciences, NRC.

Table 9-20 Body Condition Scoring System for Sheep

Score	Description
0	Animal is extremely emaciated and at the point of death. No muscular or fatty tissue can be detected between the skin and the bone.
1	The spinous processes are prominent and sharp. The transverse processes are also sharp; the fingers pass easily under the ends, and it is possible to feel between each process. The eye muscle areas are shallow with no fat cover.
2	The spinous processes still feel prominent but also smooth, and individual processes can be felt only as fine corrugations. The transverse processes are smooth and rounded, and the fingers can be passed under the ends with a little pressure. The eye muscle areas are of moderate depth but have little fat cover.
3	The spinous processes are detected only as small elevations; they are smooth and rounded, and individual bones can be felt only with pressure. The transverse processes are smooth and well covered, and firm pressure is required to feel over the ends. The eye muscle areas are full and have a moderate degree of fat cover.
4	With pressure the spinous processes can just be detected as a hard line between the fat-covered muscle areas. The ends of the transverse processes cannot be felt. The eye muscle areas are full and have a thick covering of fat.
5	The spinous processes cannot be detected even with firm pressure, and there is a depression between the layers of fat where the spinous processes would normally be felt. The transverse processes cannot be detected. The eye muscle areas are very full and have a very thick fat cover. Large deposits of fat may be seen over the rump and tail.

From Russel A: Body condition scoring of sheep, *In Pract*, 6:91, 1984.

9.3.3 Treatment of Obesity

Overweight and obese horses and ruminants should lose weight to extend life span and to improve production efficiency. In many cases a reduction in energy intake can be achieved by simply eliminating excess calories from grain or supplemental feeds. Animals that fail to lose weight after 1 to 2 months after a reduction in calories require a more aggressive weight loss program, which may include reformulation of their ration and the gradual implementation of an exercise program. Voluntary activity in animals that are turned out in pasture is rarely high enough to promote weight loss. Obese laminitic horses present a difficult challenge because exercise may not be practical, and weight loss must rely solely on dietary energy restriction.

Horses and companion ruminants that require a managed weight loss program should have the energy content of their diet evaluated by the veterinarian. The actual energy intake should be compared against the energy requirement for the animal's current lifestage (see Tables 9-11 to 9-17). The animal's current calorie intake should be reduced by 10% to 20% at the start of the weight loss program. Dietary protein should not be restricted. Supplemental feeds and treats should be reduced or eliminated from the diet, and only high-quality forage should be fed.

Feeding straw should be avoided because gastrointestinal complications including impaction colic could develop. A vitamin and mineral supplement should be fed during a weight loss program to ensure that the diet

meets nutrient requirements. To prevent boredom, small amounts of forage should be fed frequently. When horses are being fed, hay can be placed in a double hay net or hay bag, or a restricted feeder (The Grazer Hay Feeding Machine) can be used to decrease the rate of intake. The target weight loss goal is between 0.5% and 2% of the original body weight each week. A weight tape should be used to assess the horse's weight if a scale is not available. A BCS should be assigned to the animal at the start of the weight loss program. The body weight and BCS should be assessed every month to track changes in the animal's weight.

168

169

Table 9-21 Body Condition Scoring System for Horses

Score	Description
1	Poor. Animal is extremely emaciated. Spinous processes, ribs, tailhead, tuber coxae, and tuber ischii project prominently. Bone structure of the withers, shoulders, and neck is noticeable. No fatty tissue can be felt.
2	Very thin. Animal is emaciated. There is a slight fat covering over the base of the spinous processes; the transverse processes of the lumbar vertebrae feel rounded. Spinous processes, ribs, tailhead, tuber coxae, and tuber ischii are prominent. Bone structure of the withers, shoulders, and neck is faintly discernible.
3	Thin. Fat buildup is present about halfway on the spinous processes; the transverse processes cannot be felt. There is a slight fat cover over the ribs. Spinous processes and ribs are easily discernible. Tailhead is prominent, but individual vertebrae cannot be visually identified. Tuber coxae appear rounded but are easily discernible; tuber ischii are not distinguishable. Bone structure of the withers, shoulders, and neck is accentuated.
4	Moderately thin. Negative crease can be seen along the back. Faint outline of ribs is discernible. Tailhead prominence depends on conformation; fat can be felt around tailhead. Tuber coxae are not discernible. Withers, shoulders, and neck are not obviously thin.
5	Moderate. Back is level. Ribs cannot be visually distinguished but can be felt easily. Fat around tailhead is somewhat spongy. Withers appear rounded over spinous processes, and shoulders and neck blend smoothly into the body.
6	Moderately fleshy. Slight crease may be seen down the back. Fat over ribs is spongy, and fat around tailhead is soft. Fat is beginning to be deposited along withers, behind shoulders, and along neck.
7	Fleshy. Crease may be seen down the back. Individual ribs can be felt, but there is noticeable filling of fat between ribs. Fat around tailhead is soft. Fat is deposited along withers, behind shoulders, and along neck.
8	Fat. Crease is seen down the back. Ribs are difficult to feel. Fat around tailhead is very soft. Areas along withers and behind shoulders are filled with fat, and neck is noticeably thickened. Fat is deposited along inner thighs.
9	Extremely fat. Obvious crease is seen down the back. Patchy fat appears over ribs. Bulging fat is seen around tailhead along withers, behind shoulders, and along neck. Fat along inner thighs may cause thighs to rub together. Flank is filled with fat.

From Henneke GD, Potter GD, Kreider JL, Yeates BF: Relationship between condition score, physical measurements and body fat percentage in mares, *Equine Vet J*, 15:371, 1983.

Owner compliance is essential during a weight loss program for horses and companion large animals. Owners should be encouraged to keep a weight loss journal and to include digital pictures to assess the animal's BCS during the program. Excessive, rapid weight loss should be avoided. Weight loss programs should be approached with caution in animals that are either pregnant or lactating. Once the animal has achieved the ideal body weight and BCS, it should be placed on a maintenance ration and exercise program that will ensure that the ideal weight is maintained.

In a production management setting the ration should be evaluated and revised to reduce calories while maintaining sufficient energy intake to maximize reproduction or milk production. Care should be taken to ensure the animals consume an adequate concentration of vitamins and minerals to meet their requirements when they are fed an energy-restricted ration.

9.4 PICA

Pica (geophagia) is defined as a depraved or abnormal appetite. It is usually associated with animals that chew or eat wood (fences, trees, buildings), dirt, bones, or other inanimate objects not usually considered feedstuffs. The mechanism or mechanisms of pica are not yet understood. Pica has been associated with PCM, parasitism, obesity, and deficiencies of phosphorus, salt, protein (kwashiorkor), and micronutrients. Diagnosis is by observation or history or both. The main emphasis must be placed on identification and resolution of the primary problem. Pica must be differentiated from abnormal behavior associated with central nervous system diseases, bovine ketosis, and equine behavioral abnormalities associated with boredom.

10 Chapter 10 Alterations in Urinary Function

Consulting Editors

David C. Van Metre

10.1 DYSURIA AND STRANGURIA

Dysuria is defined as difficult or painful urination. *Stranguria* is defined as straining to urinate, with the normal rate and flow of voiding being decreased and the effort required to void often increased. These two clinical signs are often present simultaneously in large animals with lower urinary tract disease, and because these signs are often difficult to distinguish from each other, they are considered together in this section. The most common causes of dysuria and stranguria are urethral obstruction, inflammation of the urethra and/or the bladder, and neurologic conditions that prevent normal emptying of the bladder. Adhesions between the bladder and other structures in the abdominal or pelvic cavities can create mechanical interference with bladder emptying, resulting in dysuria and stranguria.

Urinary incontinence is defined as the involuntary voiding of urine. It is most frequently indicative of impaired neuromuscular control of urination. Evaluation of neurologic control of urination is discussed later in this section. Incontinence may also occur with severe cases of lower urinary tract trauma and inflammation. In young animals, congenital abnormalities such as ectopic ureter must be considered in the differential diagnosis for incontinence.

The horse voids urine very actively and forcefully. Both male and female adult horses may briefly groan and strain slightly during normal urination. This should not be misinterpreted as dysuria or stranguria. In other large animal species, urination is more passive, and straining or groaning normally is not observed. Conditions in which a horse may appear to have dysuria include lower urinary tract disease, abdominal pain, peritonitis, pleuritis, severe musculoskeletal disease, or neurologic disease. With any of these conditions, the horse may attempt to posture and urinate but may not be able to increase intraabdominal pressure sufficiently to allow complete voiding.

Signs of dysuria and stranguria include treading, repetitive switching or flagging of the tail, pollakiuria (frequent voiding of small amounts of urine), constant urine dripping, flatulence during voiding, and retention of the urination posture for several seconds after voiding has ceased. Urine scalding of the perineal region or rear legs may be noted in either ruminants or horses with dysuria or stranguria. Vocalization during urination may accompany dysuria, particularly in goats. While straining to void, the affected animal may show forceful contractions of the abdominal musculature. Male horses and ruminants that are experiencing dysuria or stranguria typically stand with the back slightly extended (mild lordosis), with the front legs held further ahead of the body and the hind feet positioned farther behind the body than normal (Fig. 10-1).

Dysuria or stranguria in large animal species may be confused with tenesmus. This is most frequently a dilemma in neonatal foals with a ruptured bladder or meconium impaction. However, with tenesmus the rear feet of the foal are positioned slightly more anteriorly than with stranguria or dysuria. Stranguria may be severe enough in some cases to induce secondary rectal prolapse; therefore, when examining an animal with rectal prolapse, the clinician must establish whether or not the underlying cause might be urinary tract disease.

10.1.1 Approach to Diagnosis of Dysuria and Stranguria

As for other medical problems, the signalment, onset of signs, duration, progression, and response to treatment should be established. Certain signalment and historical data can lend important clues for evaluation of specific causes. For example, urethral calculi should be suspected immediately in castrated ruminants on high-grain diets. A history of one or more horses showing clinical signs of spinal cord disease, respiratory disease, stranguria, or urinary incontinence should immediately lead the practitioner to consider equine herpesvirus-1 myelitis in the differential. A history of dysuria or stranguria that develops after parturition usually indicates an injury to the lower urinary tract. Parturient damage to the normal structure of the vagina and vestibule can increase the animal's risk of subsequent urinary tract infection. A full physical examination should be performed because abnormal urination may be a sign of disease in other body systems, such as those characterized by diffuse muscular weakness. Common causes of dysuria, stranguria, and urinary incontinence are shown in Box 10-1.

10.1.1.1 URINATION (MICTURITION)

When possible the animal should be observed urinating, and a sample of urine should be collected for dipstick urinalysis, measurement of specific gravity, and, when indicated, sediment examination. Urination can be induced in female cattle by gently rubbing the perineum immediately ventral to the vulva (Fig. 10-2). In male cattle, the examiner may induce urination by placing a finger into the preputial cavity and gently rubbing the preputial mucosa. In ewes, urination can be prompted by holding off the nose until the ewe struggles; urination typically occurs at this point. Obviously, this procedure should not be performed on ewes in shock or those with poor cardiac or respiratory function. In horses, goats, and male sheep, the examiner simply has to wait until the animal is ready to void, although urination may be prompted by placing the animal in a freshly bedded stall. Recumbent animals will often void soon after standing.

10.1.1.1.1

Box 10-1 Causes of Dysuria, Stranguria, and Urinary Incontinence in Horses and Ruminants

Urinary calculi

Penile, vaginal, urethral, or preputial trauma

Smegma accumulation (E)

Penile masses or encircling hair rings

Habronemiasis (E)

Ulcerative posthitis and vulvovaginitis (R)

Adhesions of the bladder

Urachal infection or abscesses

Rectovaginal fistula

Hemorrhage into the urinary tract

Ruptured urethra, bladder, or ureter

Viral infections of the genitalia

Vaginal prolapse

Impending parturition

Prolapsed bladder (postpartum)

Urinary tract infection

Urinary calculi

Bladder neoplasia
Estrogen-responsive dysuria (E)
Ectopic ureter
Equine neonatal maladjustment (E)
Cantharidin (blister beetle) toxicosis (E)
Prolonged recumbency
Equine herpesvirus-1 myelitis (E)
Sorghum cystitis (E)
Rabies
Epidural lymphosarcoma
Other forms of severe spinal cord disease
Pelvic or sacral fracture
Laminitis
Myopathy
Painful conditions of the abdomen or abdominal wall
Painful conditions of the thorax or thoracic wall

E, Found only in horses; *R*, found only in ruminants.

* A detailed discussion of interpretation of urinalysis is covered in Chapter 22.

10.1.1.2

EXAMINATION OF THE GENITALIA

The male's preputial hairs and the female's perineal region should be closely inspected for the presence of blood, exudate, or crystalline debris. The urethral orifice can be visualized in many males, but mild sedation and/or epidural anesthesia may be necessary to induce sufficient relaxation of the retractor penis muscles. In bulls and steers, transrectal massage of the pelvic segment of the urethra may stimulate penile relaxation to enable penile visualization. In prepubescent ruminants, the frenulum often prevents complete exteriorization of the penis for examination of the urethral orifice; general anesthesia may be needed to induce sufficient relaxation. The glans penis and urethral orifice should be carefully examined for masses such as papillomas, evidence of trauma, encircling hair rings and embedded foreign bodies (e.g., grass awns), and lesions of the urethral mucosa. An attempt should be made to exteriorize the penis and examine the urethral process in male small ruminants, as urinary calculi often become enlodged at this site (Chapter 34).

If swelling or pain is found on palpation of the most distal part of the equine penis, it may be necessary to tranquilize the horse so that this area can be examined more closely for signs of habronemiasis, neoplasia, or traumatic injury. An accumulation of smegma, composed of mucus and cellular debris, may cause preputial swelling and dysuria in adult male horses. Smegma usually can be found as a hard, waxy mass in the urethral diverticulum. Preputial swelling without pain or discharge may be seen in equine Cushing's syndrome (Chapter 41).[1]

In the male the penis and the urethra should be palpated percutaneously from the perineum to the sheath. Swelling, pain, abnormal urethral pulsations, and calculi enlodged in the urethra may be detected. Marked swelling along the ventral body wall in a bull or steer with active or recent dysuria or stranguria strongly suggests a urethral rupture. Urethral calculi are most commonly lodged just below the anus in male horses, and these can occasionally be palpated on the midline of the perineum.

The vulva, caudal vagina, and urethral orifice should be visualized and palpated in dysuric or stranguric females. Sacrocaudal epidural anesthesia may facilitate examination if painful lesions are present. In females of breeding age the cervix should be visualized or palpated and the uterus evaluated by palpation or ultrasonography, as the pollakiuria and apparent dysuria that may occur at the onset of parturition may be the primary complaint of a novice or uninformed observer. Previous dystocia can result in sufficient soft tissue trauma, laceration, swelling, and pelvic neuropraxia to induce dysuria or stranguria. The ventrum of the tail, perineum, udder, and hindlimbs should be examined for adhered blood or exudate from the female's reproductive or urinary tract. 171 172

10.1.1.3

RECTAL EXAMINATION

In adult horses and cattle, rectal palpation should be performed when dysuria and stranguria are present. Before examination the clinician should take careful note of the tail and anal tone of the animal; reduction of either or both may indicate underlying neurologic or muscular disease. At the onset the examiner must take care not to place his or her hand and wrist too far forward in the rectum because abnormalities of the trigone and pelvic segment of the urethra may be missed, as may calculi lodged at the junction of the pelvic and perineal segment of the urethra. The caudal extent of the pelvic cavity should be carefully evaluated for masses that might mechanically interfere with voiding. The bladder is typically located on the midline at the level of the pubic brim. Its presence in the caudal pelvic cavity, particularly in the standing animal, may suggest pelvic entrapment of the bladder.

Bladder distension is commonly found in persistently recumbent horses and cattle, and the bladder is often positioned further caudally than in standing animals. In the horse, bladder distention may also be found with abdominal or thoracic pain. Apparently, the abdominal pressure necessary to empty the bladder incites sufficient pain of diseased structures to cause reluctance to void. Musculoskeletal and neurologic disease may also result in bladder distension. These other possibilities should be investigated when bladder distension is detected, yet no primary disease is found in the urinary tract.

A careful rectal examination of the bladder and the proximal urethra of the horse might allow identification of urethral or cystic calculi. Most cystic calculi in the horse are singular and located in the trigone of the bladder and are best palpated with only the hand and wrist in the rectum. If there is a large amount of urine in the bladder, the stone may not be palpable; transrectal ultrasound examination may enable visualization of the stone. Sabulous calculi may be found in horses with stranguria or urinary incontinence, and on rectal examination the clinician may interpret the palpation findings as a bladder tumor or large stone.[2] If a urinary calculus is detected in the horse, an ultrasound examination of the entire urinary tract should be performed, because some horses with cystic calculi may have other stones in one or both kidneys.

10.1.1.4

NEUROLOGIC EXAMINATION

If bladder dysfunction is not caused by structural abnormalities, trauma, or infectious disease, a thorough neurologic examination should be conducted. If neurologic dysfunction is suspected, an attempt should be

made to determine whether the primary lesion is affecting the detrusor muscle or the urethral sphincter muscles of the bladder. This determination is often helpful in localizing the lesion and is important when selecting treatment.

When bladder paralysis is caused by upper motor neuron (UMN) dysfunction, signs of UMN dysfunction may be evident in the rear limbs. The animal frequently postures and strains to urinate but voids only a small amount of urine, because the striated urethral muscles are disinhibited from higher centers and their resultant increased tone impedes urine outflow from the bladder. Frequent, small-volume urine egress from the distended bladder occurs when the animal responds to the urge to void, or when the bladder undergoes reflex contraction.

With severe disease of the sacral spinal cord or sacral nerve plexus, lower motor neuron (LMN) input to the detrusor muscle is impaired or absent. Urinary incontinence is often the predominant clinical sign (e.g., cauda equina neuritis in horses or lymphoma in cattle). The bladder usually is moderately to severely distended, and urine can be expressed easily if pressure is applied to the bladder during rectal examination. With LMN dysfunction urine may also be voided as the animal walks. Voluntary or involuntary voiding is often incomplete, leading to retention of urine in the bladder. This, in turn, increases the patient's risk of urinary tract infection and, in horses, sabulous calculi accumulation in the bladder. Other neurologic signs involving the sacral and coccygeal nerves may be apparent, such as decreased tail and anal tone and atrophy of the gluteal or tailhead musculature. Ataxia of the rear limbs may or may not be present with an LMN bladder. Urethral and bladder pressure profiles can be determined to better assess the location of the lesion.[3–5]

10.1.1.5

URINALYSIS AND URINE CULTURE

If dysuria, incontinence, or stranguria are believed to be caused by an inflammatory disease of the urethra or bladder, the absence or presence of infection should be determined (see section on pyuria).

10.1.1.5.1

Small Ruminants and Neonates

Ultrasonography and transabdominal palpation are useful for evaluation of the urinary tract. In these animals a distended bladder usually can be palpated by simultaneously placing one hand on each side of the caudal ventral abdomen at the level of the pelvic brim and pressing the fingers of each hand toward the abdominal midline. If the bladder has been ruptured, it will be difficult to identify by palpation but ascites can be detected. Digital rectal examination of the pelvic segment of the urethra can be performed in neonatal cattle and horses and in small ruminants. The umbilicus should be carefully palpated in neonates with dysuria or stranguria because urachal abscesses and adhesions to the bladder may impair voiding. An infected urachus will occasionally communicate with the bladder lumen, creating concurrent septic cystitis.

Ectopic ureter(s) should be considered in young animals with persistent urinary incontinence; stranguria and dysuria are less common primary complaints. In affected females, vaginal urine pooling is often present. Vaginoscopic or cystoscopic examination can be performed, but the opening of the ectopic ureter can be difficult to locate during routine examination. Intravenous, positive-contrast pyelography may be required to locate the ectopic structure(s). As for all congenital defects, a careful assessment for defects in other organs should be performed.

10.2 HEMATURIA AND PIGMENTURIA

Hematuria is defined as blood in the urine. It may appear as occult blood detected during urinalysis, as uniformly red-colored urine throughout urination, or as blood clots passed at any phase of urination. If large clots are present, obstruction of the urinary tract may occur, resulting in concurrent stranguria and dysuria. *Pigmenturia* is defined as the presence of abnormal pigment in the urine; in large animals such pigments are usually limited to hemoglobin or myoglobin. Hemoglobin, myoglobin, and blood all cause a positive reaction for blood and protein on a urine dipstick test. Certain oxidizing disinfectants can also trigger a positive reaction for blood on these strips.

Hematuria can be easily distinguished from hemoglobinuria and myoglobinuria if clots of blood are present in the urine. Also, when scattered spots of color change are evident on the blood reagent pad of the urine dipstick, the reaction pattern reflects the presence of small aggregates of red cells having been deposited on the pad. Otherwise, differentiation requires that the discolored urine be centrifuged and the sediment examined. Again, prompt examination of urine sediment after collection is required, as intact red cells in urine may lyse during storage. Hematuria is characterized by red, pink, or brown-colored urine that clears partially or entirely after centrifugation, resulting in a pigmented pellet of sediment. Red cells or red cell “ghosts” are visible in the sediment of animals with hematuria.

172

173

Urine containing hemoglobin is clear to dark red in color, depending on the concentration of hemoglobin in the sample. If visibly discolored, the urine does not clear when centrifuged. Sediment findings vary according to the underlying disease, and hyaline or cellular casts may be seen if pigment nephropathy is present. Animals with hemoglobinuria are often experiencing intravascular hemolysis, which leads to passage of hemoglobin from the plasma into the tubular fluid of the nephrons. The serum or plasma of these animals may be pink in color. Mucous membrane pallor or icterus may be evident, and tachycardia and tachypnea are present when red cell destruction is rapid and extensive. The packed cell volume may be decreased at the time of initial examination, or it may decrease progressively over 12 to 24 hours of monitoring. Release of hemoglobin from red blood cells may result in elevation of the plasma and serum total protein concentration. The clinician should note that hemoglobin is potentially nephrotoxic, and renal function and hydration should be carefully evaluated and monitored in such cases.

Urine containing myoglobin is clear to dark red or brown in color, depending on the concentration of myoglobin in the sample (Fig. 10-3). If visibly discolored, urine containing myoglobin does not clear when centrifuged. Sediment findings are variable but can include hyaline or cellular casts if pigment nephropathy is present. Myoglobin can be differentiated from hemoglobin in urine through ammonium sulfate precipitation, electrophoresis, or spectroscopy. Animals with myoglobinuria have muscle necrosis or injury, which leads to release of myoglobin from damaged muscle cells into the plasma. Myoglobin then passes from the plasma into the tubular fluid. Extensive muscle trauma (e.g., dog attacks, trailer accidents) or primary diseases of muscles can induce myoglobinuria. Affected animals may show abnormal stance or gait or other evidence of muscle swelling, pain, or weakness. The serum activity of the enzymes creatine phosphokinase (CPK), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) is variably increased, depending on the duration and severity of muscle injury. As for hemoglobinuria, the presence of myoglobinuria should alert the clinician to assess and monitor renal function and hydration, as the persistence of myoglobin in the tubular fluid of the nephrons can induce tubular necrosis.

Fig. 10-3 Normal equine urine *(left)* and urine with severe myoglobinuria *(right)*. Urine containing myoglobin is not always so markedly discolored. *Photo courtesy of Paul S. Morley, DVM, PhD, DACVIM.*

10.2.1

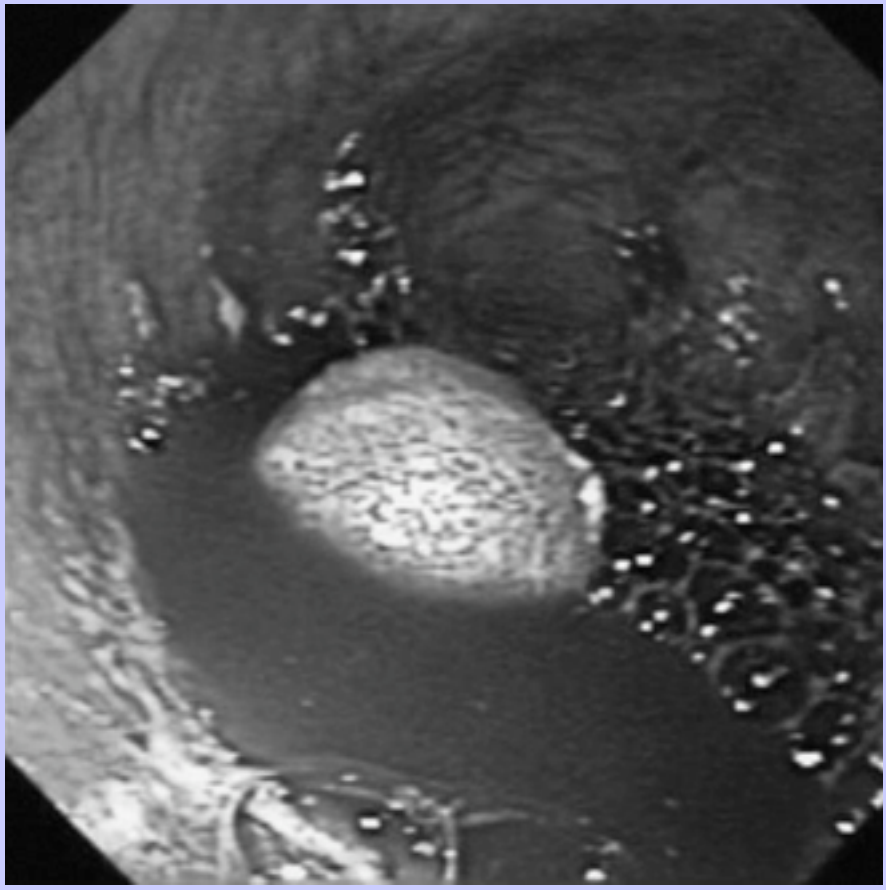
Approach to Diagnosis of Hematuria and Pigmenturia

The history should include data on recent infectious diseases, exercise, diet, and treatment. Hematuria after exercise may indicate the presence of erosions in the urinary tract mucosa, anomalous vascular structures, or mucosal trauma from uroliths (Fig. 10-4). Ingestion of certain toxins (e.g., cantharidin, bracken fern) can create hematuria; hemoglobinuria can result from exposure to hemolytic toxins, such as red maple leaves, copper, onions, and certain bacterial toxins. Intravenous infusion of markedly hypotonic or hypertonic fluids, such as water and undiluted dimethyl sulfoxide (DMSO) solution, respectively, can result in intravenous hemolysis and hemoglobinuria. The potential for exposure to gossypol and ionophores should be investigated as a cause of myoglobinuria. Certain viral and bacterial infections, such as streptococcal infections in horses, can induce myopathy and myoglobinuria. A recent history of heavy exertion or abnormally high ambient temperature (heat stroke) may exist in cases of myopathy with myoglobinuria. A previous history of recurrent exercise intolerance or muscle dysfunction may be evident in certain inherited, idiopathic, or diet-associated cases of rhabdomyolysis. Prolonged recumbency, as occurs under general anesthesia, can induce sufficient pressure myopathy to cause myoglobinuria. Rarely, idiosyncratic responses to medications can induce hemolysis or muscle injury, resulting in hemoglobinuria and myoglobinuria, respectively.

173

174

Fig. 10-4 Endoscopic view of a calculus in the lumen of a horse's bladder. Note the presence of hematuria. *Photo courtesy of Carl Soffler, DVM.*



A full physical examination should be conducted. The patient with potential hematuria should be carefully examined for clinical signs suggestive of impaired coagulation. A positive blood reaction on urine dipstick analysis can occur with true hematuria, hemoglobinuria, myoglobinuria, or contamination of the urine with reproductive or fecal blood. Severe vulvitis often develops in female horses and ruminants with profuse diarrhea as a result of chronic contact of the vulvar mucosa with fecal contents. A trace reaction for blood is often evident in the urine of these animals; however, the possibility of hemorrhage from tubular injury caused by hypovolemia should be considered as well. Common causes of hematuria and pigmenturia are listed in Box 10-2.

Lesions of the urethra most often produce hematuria at the beginning of urination, although in a male horse with proximal urethral disease, this hemorrhage may be seen only at the end of urination.[6,7] These geldings and stallions often show hematuria associated with a vascular fistula or cavernosal rupture in the most proximal urethra.[6,7] Hematuria that originates from the bladder is most likely to be seen or appear more pronounced at the end of urination. Hemorrhage originating from the upper urinary tract would likely be more pronounced at the end of urination, but voluminous or continuous hemorrhage in the upper tract might result in hematuria seen throughout urination. If the urine discoloration appears uniform throughout urination and no clots are obvious, the veterinarian must first determine that the discoloration is hematuria and not hemoglobinuria, bilirubinuria, or myoglobinuria. This can be accomplished by routine dipstick urinalysis; urine sediment examination; assessment of the patient's packed cell volume, plasma protein concentration, and serum muscle enzyme activities; and visualization of the color of the plasma and mucous membranes.

Hematuria often accompanies pyuria and bacteriuria in urinary tract infection. If hematuria is confirmed and urinary tract infection or trauma is not the cause, rectal examination may reveal calculi or tumors in the proximal urethra or bladder. Introduction of the hand and wrist into the rectum is usually sufficient for careful palpation of the pelvic segment of the urethra and bladder trigone. Examination of the urethral orifice, along with endoscopic examination of the urethra and bladder, is necessary if the lesion cannot be detected during rectal or physical examination.

During endoscopic examination of the urethra and bladder, if the source of hemorrhage is not apparent, the openings of the ureters and the color of the urine coming from both of them should be visualized. This is best performed after suctioning urine from the bladder and then distending the bladder with air, taking care that bubbling of the urine does not occur. The ureteral opening can be seen dorsally as the scope is first introduced into the bladder. The two openings can be visualized simultaneously by passing the scope farther into the bladder and retroflexing the scope caudally until the entire trigone area is visualized. If hemorrhage is seen to originate from one or both ureteral openings, the next diagnostic step is ultrasound examination the kidneys and ureters, as the hemorrhage has now been localized to the upper urinary tract.

10.3 PYURIA

Pyuria is defined as gross or microscopic purulent exudate in the urine. Dysuria, stranguria, pollakiuria, crystalluria, urine scalding of the perineum, or hematuria may accompany the pyuria. Pyuria may result from septic or nonseptic inflammatory disease. Causes of pyuria are listed in Box 10-3. Normal equine urine is turbid owing to the presence of mucus and calcium-based crystals.

10.3.1

Box 10-2 Causes of Hematuria and Pigmenturia in Horses and Ruminants

10.3.1.1

HEMATURIA

Habronemiasis (E)

Urinary calculi

Vascular anomaly, corpus cavernosum rupture (proximal dorsal urethral hemorrhage in males) (E)

Penile, vaginal, preputial, or urethral trauma

Penile masses, encircling hair rings

Neoplasia

Bleeding diatheses (e.g., warfarin, disseminated intravascular coagulation [DIC])

Cantharidin (blister beetle) poisoning (E)

Enzootic hematuria (R)

Urinary tract infection

Leptospirosis

Nephritis

Aberrant parasite migration within the urinary tract

Exercise-induced hematuria (E)

Renal papillary necrosis (e.g., related to nonsteroidal antiinflammatory drugs [NSAIDs])

Contamination of urine with oxidant disinfectants

Hemorrhage from the reproductive tract in females

Admixture of fecal blood with urine

10.3.1.2 HEMOGLOBINURIA

Intravascular hemolysis:

Intravenous (IV) hypotonic fluid administration

IV hypertonic fluid administration (e.g., dimethyl sulfoxide [DMSO])

Excess water intake, water intoxication

Red maple intoxication (E)

Clostridium hemolyticum infection (redwater)

Onion and *Brassica* species (rape, kale, etc.) intoxication

Leptospirosis

Hepatic failure

Neonatal isoerythrolysis

Copper intoxication

10.3.1.3 MYOGLOBINURIA

Exertional, capture rhabdomyolysis

Toxic myopathies (e.g., *Cassia* species, ionophores, gossypol)

Myopathy associated with streptococcal infections (E)

Clostridial myonecrosis

Viral myopathies (influenza, equine herpesvirus [EHV], bluetongue)

Nutritional myodegeneration

Postanesthetic myoneuropathy

Hereditary, congenital myopathies

E, Found only in horses; *R*, found only in ruminants.

10.3.2

Approach to Diagnosis of Pyuria

The history should be taken, and a complete examination of the entire urinary tract should be performed, including rectal palpation or transabdominal palpation of the bladder. Although cystitis may be characterized by a thickened bladder wall, this is often difficult to detect, and ultrasonographic examination may be necessary to accurately detect this lesion. In males the accessory sex glands should be carefully examined, as exudate from these structures may be admixed with urine. Predisposing factors, such as urinary calculi, dystocia, abnormal urethral or genital structure, and neurologic diseases should always be considered.

174

175

10.3.2.1

Box 10-3 Causes of Pyuria in Horses and Ruminants

Penile, vaginal, urethral, or preputial trauma

Penile masses or encircling hair rings

Ulcerative posthitis and vulvovaginitis (small ruminants)

Viral infections of the genitalia

Rectovaginal fistula

Urinary calculi

Urinary tract infection (urethritis, cystitis, ureteritis, and/or pyelonephritis)

Exudation from the reproductive tract in females

Exudation from accessory sex glands in males

Nephritis

Leptospirosis
Urinary tract neoplasia
Admixture of exudate from the female reproductive tract

Pyuria is confirmed by obtaining a midstream or catheterized urine sample (or both) and quantitating the number of white blood cells and bacteria in the urine sediment. Evaluation of urine sediment within 30 to 60 minutes of collection enables preservation of the greatest cytologic detail. Pyuria is confirmed by the presence of >10 white blood cells per high-power microscopic field of a midstream-voided or catheterized sample. When bacterial infection is the cause, there are typically > 20 organisms visible per high-power field. The cytologic features of urine sediment are greatly influenced by the method of collection, rigor of aseptic technique, and degree of contamination of the prepuce, vulva, and urethral orifice. Catheterization can be used to obtain urine from the bladder of most male and female horses and female ruminants. In male ruminants the urethral recess (diverticulum) prevents retrograde catheterization of the bladder, and collection of a midstream sample is usually the sole option. Cystocentesis of a large animal with a urinary tract infection carries the risk of induction of septic peritonitis.

Quantitative cultures of the samples should be performed soon after collection in order to prevent false increases in the colony count that can occur from bacterial proliferation in the sample during storage. The results of quantitative culture are greatly influenced by the method of collection and the degree of contamination of the prepuce and vulva. In specimens collected by midstream free catch, bacterial counts greater than 1×10^4 bacteria per milliliter of urine are indicative of urinary tract infection if compatible dipstick and sediment examination findings are present. Normal male and female horses have less than 20,000 colony-forming units (CFU) per milliliter of urine on a free catch sample and less than 500 CFU/mL on a catheterized sample.[8] A culture that yields a large number of mixed growth may reflect heavy contamination of the vulva or penis, fecal admixture, or delay before culture was initiated.

Once pyuria is confirmed, the clinician should next determine the location or origin of the pyuria, the cause, and any predisposing conditions. In females the reproductive tract should be evaluated to confirm that it is not the source of the exudate, as mixing of urine and exudate in the urethra and vestibule may result in a spurious diagnosis of pyuria. Similarly, trauma or inflammation of the glans penis or prepuce can result in admixture of exudate with urine, as often occurs in cases of ulcerative posthitis in rams and bucks. Inflammatory diseases of the urethra and bladder usually produce obvious clinical signs of dysuria but minimal to no signs of systemic disease. Low-grade fever may be present in occasional cases of cystitis, but affected animals rarely appear to be systemically ill.

If the pyuria originates from the upper urinary tract (ureters and kidneys), the animal is usually persistently or intermittently febrile and shows systemic signs of disease. Inflammation of the ureter(s) and kidney(s) may result in colic. The rectal examination may reveal enlargement of one or both ureters, pain on palpation, and possibly an enlargement or abnormal shape (or both) of the left kidney. If grossly enlarged, the right kidney occasionally can be palpated per rectum in the horse or cow. In cows and heifers, vaginal palpation may reveal thickening and pain of one or both ureters. Changes suggestive of inflammation are often present on the complete blood count. Although cytologic examination of the urine may indicate pyuria, bacteriuria may be inconsistently found,

particularly if the infection originates from a nephrolith. Casts of exudate, blood, protein, or cellular debris may be seen the urine sediment in cases of pyelonephritis.

An ultrasound examination of both kidneys and ureters should be performed in all animals with evidence of upper urinary tract infection. The technique for ultrasound examination of the urinary tract is described in Chapter 34.

If *Leptospira interrogans pomona* is suspected as a cause of pyuria, urine sediment should be placed on a microscope slide, air dried, and examined by fluorescent antibody for *Leptospira* antigen.[9] Polymerase chain reaction testing for this organism can be performed on urine sediment; in cattle, greater sensitivity may be achieved by obtaining a urine sample after administration of furosemide.[10]

10.4 CRYSTALLURIA

Crystalluria is defined as the presence of crystals in the urine. Calcium carbonate and calcium phosphate crystals are abundant in normal equine urine; these, along with mucus, impart a turbid, slightly opaque quality to normal equine urine. Herbivore urine is normally alkaline, which reduces the solubility of certain calcium- and phosphate-based compounds in urine, inducing crystal development. Small numbers of calcium phosphate, calcium carbonate, or calcium oxalate crystals may be present in highly concentrated ruminant urine. In such cases crystalluria should be considered an incidental finding if the animal is healthy and free from signs of urinary tract disease. However, in male ruminants, heavy or persistent crystalluria may indicate the potential risk of urolithiasis because the combination of highly concentrated urine and urinary mineral precipitation is considered instrumental in calculogenesis. A precautionary review of diet, salt intake, and water management may be indicated in such cases. High dietary intake of calcium and oxalates has been hypothesized to be the cause of heavy calcium oxalate crystalluria in a goat.[11]

Crystalluria presents a medical problem when crystals enlarge through precipitation, causing microscopic or gross traumatic injury to the urinary epithelium and urinary tract obstruction. When crystals coalesce and enlarge to form calculi (uroliths), the calculi may remain occult or cause disease through trauma to and obstruction of the urinary tract. As a result, the clinician usually detects crystalluria in these animals during the diagnostic workup for hematuria, dysuria, stranguria, pyuria, or signs of urinary tract obstruction. It is critical to note that the *absence* of crystalluria does not indicate that the urinary tract is free of calculi or renal mineralization.[12–14] Causes of crystalluria are listed in Box 10-4.

175

176

10.4.1 Box 10-4 Causes of Crystalluria in Horses and Ruminants

Normal calcium-based crystalluria of horses

Highly concentrated or alkaline urine

Urolithiasis

Urinary tract infection

Ethylene glycol intoxication

Intoxication with oxalate-containing plants

Parenteral vitamin C

10.4.2 Approach to Diagnosis of Crystalluria

10.4.2.1 HISTORY

Toxins such as oxalic acid and ethylene glycol can induce calcium oxalate crystalluria, so animal access to oxalate-containing plants and storage areas or garages should be investigated. Administration of high doses of parenteral vitamin C can also induce calcium oxalate deposition in the urinary tract, and a careful history can help to include or exclude these causes from the differential diagnosis list. Previous urinary tract surgery, dystocia, or genital trauma may not directly contribute to crystalluria per se, but abnormal structure of the urinary tract, suture material retained in the tract, or loss of uroepithelial integrity can promote crystal precipitation into calculi.

10.4.2.2 PHYSICAL EXAMINATION

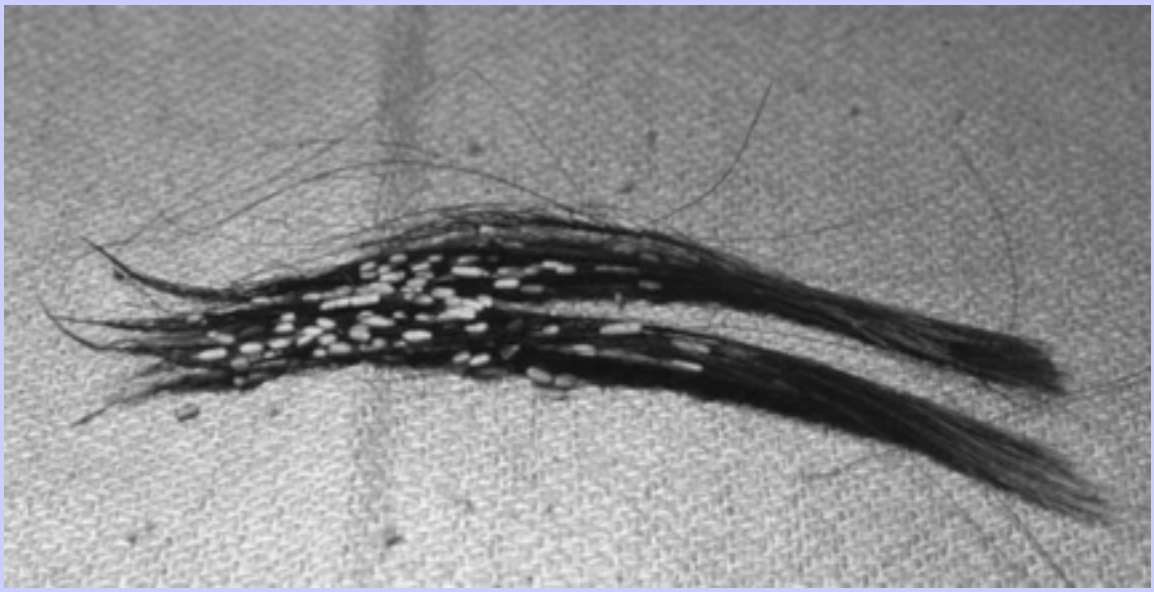
The hairs surrounding the preputial orifice or vulva should be carefully examined for visible crystals that cling to the hair (Fig. 10-5). Animals with dysuria and stranguria or incontinence may have crystals adherent to the hair of the hindlegs or tail as well. The presence of adherent crystals on hair indicates that crystalluria is heavy, and in males, given that imminent or current obstructive urolithiasis is the most important diagnosis to investigate, the clinician should determine whether or not the urinary tract is patent in such instances.

Urinary tract infection can induce microscopic crystalluria, crystal and exudate accumulation on the external genitalia, or, more rarely, calculus formation. Urease-producing bacteria may increase the pH of urine to the point of inducing precipitation of certain minerals suspended in the urine into calculi. In addition, exudation into the infected urinary tract also provides nidi for deposition of urinary minerals. The approach to urinary tract infections is discussed in the previous sections on dysuria, stranguria, and pyuria.

10.5 POLYURIA

Polyuria can be defined as the passage of abnormally large amounts of urine. This may be a normal response when excessive fluid, electrolytes, or both are presented to the tubules of a healthy kidney. It may also occur with renal failure when tubular function is impaired or when enough individual nephrons have been lost that the remaining ones are presented with excess fluid and/or solute. Polyuria is also present in central or neurogenic diabetes insipidus (caused by insufficient secretion of antidiuretic hormone [ADH]), nephrogenic diabetes insipidus (caused by diminished effect of ADH on receptors in the kidney), renal medullary washout (caused by an insufficient interstitial concentration gradient), excessive drinking (polydipsia), liver failure, fluid administration, and certain electrolyte abnormalities. Polyuria may also be evident after urinary tract obstructions have been relieved, a phenomenon termed *postobstructive diuresis*. Causes of polyuria are listed in Box 10-5.

Fig. 10-5 Crystals adherent to the preputial hairs of a steer with urolithiasis. The crystals were analyzed and found to be composed of struvite (magnesium ammonium phosphate).



10.5.1

Approach to Diagnosis of Polyuria

Evaluation of an animal with polyuria should begin with an inquiry about any history of recent disease, drug administration (e.g., diuretics, corticosteroids, xylazine), fluid therapy, change in diet, change in water quality or availability, or known laboratory evidence of renal disease. After completion of the history and a review of the patient's medical records, the initial diagnostic step is to collect a urine sample to measure the osmolality or specific gravity (UspG). If the osmolality is close to the isosthenuric range (UspG of 1.008 to 1.014), and the concentration remains similar to the plasma concentration in the face of dehydration, primary renal disease should be considered as a cause. This is typically confirmed by measuring the serum creatinine concentration, 176
although radionuclide clearance studies and/or 12- or 24-hour urinary creatinine clearance can also be performed. 177
If evidence of renal failure is not evident on these tests, a water deprivation test may be needed to determine the tubules' ability to concentrate urine. This test should be performed in a normovolemic patient with careful monitoring of patient status during the test, because the mild dehydration induced during this test may exacerbate preexisting, occult renal disease.

10.5.1.1

Box 10-5 Causes of Polyuria, Anuria, and Oliguria in Horses and Ruminants

10.5.1.1.1

POLYURIA

Excessive salt or water ingestion

Salt deficiency

Excessive intravenous fluid therapy

Acute or chronic renal failure

Central diabetes insipidus

Nephrogenic diabetes insipidus

Medullary washout

Psychogenic polydipsia

Diabetes mellitus

Liver failure

Postobstructive diuresis

Hyperglycemia

Xylazine

Corticosteroids

Diuretics

Severe deficits of chloride, potassium, or urea

10.5.1.1.2 ANURIA AND OLIGURIA

Dehydration, hypovolemia

Urinary tract obstruction (e.g., urinary calculi)

Rupture of the urethra, bladder, or ureter(s)

Acute or chronic renal failure

10.5.1.1.3 *APPARENT* ANURIA OR OLIGURIA

Painful diseases of the abdomen or abdominal wall

Painful diseases of the thorax or thoracic wall

Recumbency

Neonatal maladjustment

Patent urachus

Encephalopathies

Severe spinal cord disease

Ectopic ureter(s)

As an alternative to the water deprivation test in identifying tubular disease and dysfunction as the cause of polyuria, the fractional clearance (fractional excretion) of sodium in the urine can be measured. This test is performed on simultaneously collected urine and serum samples by measuring the creatinine and sodium in both the serum and the urine. The fractional clearance (Fc_{Na}) of sodium is then determined by the following formula:

$$Fc_{Na}(\%) = \frac{[Na_u]}{[Na_p]} \times \frac{[Cr_p]}{[Cr_u]} \times 100$$

where Na_u is the urine sodium concentration, Na_p is the plasma creatinine concentration, Cr_u is the urine creatinine concentration, and Cr_p is the plasma creatinine concentration. A fractional sodium clearance value above 1% in adult horses is suggestive of primary tubular disease,[15] particularly if the animal's diet and physiologic state are such that avid sodium conservation is expected. Fractional clearance of sodium values of up to 4% have been measured in healthy, lactating dairy cattle.[16] Thus, for this test to be valid, salt intake must be normal, the animal must not be given diuretics, and due consideration of the animal's diet and physiologic state must be given. Intravenous fluid therapy will complicate interpretation of fractional clearance values.

If the UspG or osmolality is less than that of the plasma (1.007), diabetes insipidus, psychogenic polydipsia, and renal medullary washout should be considered. Diabetes insipidus, although rare, has been reported in the horse and may be the result of inadequate secretion of vasopressin (neurogenic diabetes insipidus) or inadequate response to vasopressin in the kidney (nephrogenic diabetes insipidus).[17] However, the patient may simply be

ingesting large amounts of water as a result of high ambient temperature, so interpretation of low UspG requires due consideration of the animal's physiologic state.

10.6 ANURIA AND OLIGURIA

Anuria is defined as the absence of urine production, and *oliguria* is defined as scant or subnormal urine production. Unless the patient's history includes a careful record of urine output, these two disease conditions are often difficult to distinguish at the onset of the evaluation. Furthermore, the difficulties associated with maintaining urine collection devices in large animals make an accurate measurement of urine production difficult in many cases.

The volume of urine produced by healthy large animals varies tremendously according to breed, age, physiologic status, level of exercise, diet, and a multitude of environmental factors. Altman (1961) determined normal urine output for the large animal species to be as follows: horses, 3 to 18 mL/kg/day; cattle, 17 to 45 mL/kg/day; and sheep and goats, 10 to 40 mL/kg/day.[18] Anuria and oliguria frequently become apparent to the clinician when an azotemic animal is diagnosed with a primary disease in which renal function is commonly threatened (e.g., severe diarrhea) and urine output after initiation of fluid therapy is noted to be subnormal or absent.

If urine collection and measurement cannot be performed, the adult animal with potential anuria or oliguria can be closely watched or placed in a stall with minimal bedding or fine, fresh bedding (e.g., sawdust) in order to facilitate detection of urine on the stall floor. When indicated, fluid therapy should be initiated and expectations for urine output predicted based on the rate and route of fluid administration. Animals with painful thoracic or abdominal disease may refrain from urination, and the clinician must remember to evaluate *bladder filling* and not just the volume of urine voided. Recumbent, obtunded foals, particularly males, may not reliably void urine; monitoring bladder fill by ultrasound or placement of an indwelling urinary catheter is recommended. Urachal leakage of urine must be considered in neonates with suspected anuria or oliguria, as these animals may be observed to void less frequently than normal. Animals with encephalopathies or severe spinal cord disease may not be capable of voluntary voiding.

When evidence for anuria mounts, the clinician must determine if the urinary tract is patent and rule out the presence of rupture of the bladder, urethra, or ureters. Repeat physical examination and ultrasound of the upper and lower urinary tract and abdominal cavity is warranted in such instances. Obstructive diseases of the lower urinary tract are typically accompanied by signs of colic and stranguria. However, these signs will not be present if the patient has a preexisting rent in the urinary tract or if the animal is severely obtundent from uremia.

Oliguria is a physiologic adaptation to dehydration and can be expected in animals with prerenal azotemia. Assessment of the urine specific gravity is critical in determining the presence of renal failure in such cases. If urine cannot be collected from the dehydrated animal, fluid therapy should be initiated and the azotemia monitored. Oliguria is a relatively common feature of acute renal failure, particularly if the disease process involves obstruction of the nephron lumen with crystals, cellular debris, or proteinaceous casts. However, the volume of urine produced by the large animal in renal failure can vary greatly according to the patient's hydration status, diet, and the inciting cause. In short, urine production can be normal, increased, or decreased in renal failure. Renal failure is covered in detail in Chapter 34. Causes of anuria and oliguria are listed in Box 10-5.

10.7 UREMIA

Uremia is caused by the presence of excessive urinary constituents in the blood and their detrimental effect on a variety of organ systems. Uremia is defined as the constellation of clinical signs, impaired metabolic processes, and

alteration of the function of multiple organs that occurs as a result of failure to excrete waste products from the body via the urine. Uremia may be the result of either acute or chronic renal failure, retention of urine in the body as a result of urinary tract leakage (e.g., bladder rupture), or both. Various retained toxins are associated with the uremic process, including urea, parathyroid hormone, guanidine, phenolic compounds, and phosphorus.[19,20] The predominant clinical signs of uremia seen in large animals are depression and anorexia. Weight loss, gastrointestinal ulcers, polyuria, polydipsia, melena, and diarrhea are other noticeable effects. Oral erosions or ulcers, gingivitis, diffuse stomatitis, dental tartar, and halitosis may be evident on examination of the oral cavity. Coagulopathy and platelet dysfunction make uremic patients prone to gastrointestinal hemorrhage and impaired clotting during surgery. Pulmonary edema and uremic encephalopathy may develop in rare cases.

12 Chapter 12 Alterations in Sexual Function

Consulting Editors

Mats H.T. Troedsson

Bruce W. Christensen

12.1 ALTERATIONS IN MALE SEXUAL FUNCTION

Patrick M. McCue

Stallions, bulls, rams, and bucks intended to be used as breeding animals need to have (1) normal genital organs, (2) the libido necessary to tease females and gain an erection, (3) the physical ability to mount and intromit the penis into the female's vagina, and (4) an adequate number of morphologically normal, motile spermatozoa in each ejaculate to be considered as satisfactory breeders under natural service conditions. Digression from normal sexual function in males usually is recognized clinically by changes in sexual behavior, abnormalities or diseases of the genital organs, or a decreased pregnancy rate in dams bred. Subfertile males may be responsible for significant economic loss in the livestock industry.

12.1.1 Mechanisms of Altered Male Sexual Function

Sexual function may be altered by any of four major mechanisms: general physical abnormalities, abnormalities of the genital organs, decreased libido, and poor semen quality (Boxes 12-1 and 12-2).

The male must be mobile enough, especially in a pasture breeding program, to locate, tease, mount, and breed estrual females successfully. Musculoskeletal abnormalities may limit reproductive ability or desire. Hindlimb conformation defects in bulls and rams, degenerative joint disease involving the hock in stallions, and foot problems in rams are examples of conditions that may cause enough discomfort to interfere with the normal breeding process or prevent normal mobility, impairing reproductive performance.[1–3]

Congenital or acquired abnormalities of the genital organs, including the penis, prepuce, scrotum, testicles, spermatic cords, or accessory sex glands, can lead to altered sexual function or infertility. Congenital abnormalities such as persistent penile frenulum and penile deviations in bulls may prevent normal intromission.[4] Acquired lesions such as a penile hematoma caused by rupture of the tunica albuginea of bulls at time of service may limit sexual function by causing paraphimosis, adhesions, or sensory nerve damage.[5]

Libido is an essential component of breeding performance but may be difficult to measure during a breeding soundness examination and cannot be evaluated if semen is collected by electroejaculation. Libido has been demonstrated to be an inherited behavioral trait in bulls.[6]

Semen volume, concentration of spermatozoa, percentage of progressive motility, and percentage of morphologically normal spermatozoa are semen parameters commonly measured during a breeding soundness examination. Abnormalities of semen quality associated with decreased fertility in bulls include spermatozoa morphology and, to a lesser degree, motility.[2,4,7]

12.1.2

Approach to Diagnosis of Altered Male Sexual Function

A complete breeding soundness examination and history should be obtained, including number of females bred each year, conception rates, breeding methods (natural service or artificial insemination), and results of previous breeding soundness examinations (Box 12-3). A medical or health history, including medications, vaccinations, and previous illnesses, should be obtained. The animal should be given a general physical examination. Hindlimb conformation and the presence of degenerative joint disease, laminitis, foot abscesses, abnormal foot wear, corkscrew claw defect, weak pasterns, postleggedness, sickle hock, interdigital fibromas (bulls), foot rot, ulcerative dermatitis and pizzle rot (rams), and caprine arthritis-encephalitis (CAE) (bucks) should be noted. An ophthalmologic examination should be done to ensure that the animal has adequate vision and that no significant pathologic condition is present. A special emphasis is placed on identification of squamous cell carcinoma and pinkeye *(Moraxella bovis)* corneal lesions in bulls. Range animals showing weight loss and a decline in reproductive performance should be given an oral examination, and the parasite control program should be evaluated.

The external genital organs should be examined carefully. The penis of the stallion is easiest to examine after an erection is obtained by teasing to an estrual female. In ruminants manual palpation of the penis per rectum or by use of an electroejaculator is suitable in many cases. The penis should be normal in size and shape and free of lesions. In bulls, deviations or other abnormal configurations such as corkscrew penis may occur with use of an electroejaculator and therefore cannot be considered abnormal.[5] Rams and bucks should be carefully examined for abnormalities of the urethral process, including the presence of calculi.[8] The lesions most often observed on the penises of stallions are squamous cell carcinoma and cutaneous habronemiasis.[9,10]

Gynecomastia (C)

B, Bovine; *C*, caprine; *O*, ovine.

The prepuce should also be examined for lesions. Strictures of the preputial orifice may increase the risk of phimosis or paraphimosis. Bulls of the *Bos indicus* breeds often have a pendulous prepuce that is predisposed to traumatic injury, abscessation, stricture formation, and eversion.[5,11] Ulcerative posthitis (pizzle rot) caused by *Corynebacterium renale* in rams on a high-protein diet is the most common lesion of the prepuce in rams.[12]

The scrotum, testicles, and spermatic cords should be examined for size, consistency, symmetry, and presence of lesions. Two scrotal testicles should be present, each smooth, resilient on palpation, and freely movable. Testes volume and consequently the amount of testicular parenchyma present are highly correlated with daily sperm production in all species. Each gram of testicular tissue should produce 15 to 20 million sperm per day. In ruminants, scrotal circumference has been determined to be highly correlated with testes weight or volume. Yearling beef bulls should have a scrotal circumference of 30 cm or more, depending on the animal's age and breed.[7] In stallions, measurements of total scrotal width and, more recently, testicular volume have been evaluated and correlated to potential daily sperm production. Mature stallions should have a scrotal width of at least 8 cm. Testicular volume in stallions can be determined by the following steps[13]:

196

197

1 Measure the length (L), width (W), and height (H) of each testicle.

2 Volume of each testicle can be determined using the formula:

Testicular volume (cm^3) = 0.5233 × L × W × H

3 Add the volume of each testicle to obtain total testicular volume.

4 Expected daily sperm production (DSP) (in billions of sperm per day) can be calculated using the formula:

Expected DSP = 0.024 × (Total testicular volume in cm^3) – 1.26

10	Serologic tests

The epididymides should be palpated for position, size, and presence of lesions. The most common palpable abnormality in rams is epididymitis caused by infection with *Brucella ovis, Actinobacillus seminis*, or *Histophilus ovis*.[8,12,14] A definitive diagnosis is obtained by isolation of bacterial organisms in the semen and serologic testing.

Diseases of the accessory sex glands are diagnosed most frequently in bulls. Vesicular gland adenitis is clinically recognized by the presence of leukocytes in the semen and enlargement, induration, and loss of lobulation noted during palpation and ultrasonographic examination of the glands per rectum.[15,16]

Libido and the ability to mate should be assessed after the physical examination. The male should be teased to a female in estrus. Interest in and interactions with the female and ability to gain an erection, mount, intromit the penis into the vagina (or into an artificial vagina), and ejaculate are noted. Libido and mating ability cannot be evaluated when using an electroejaculator to collect semen from ruminants. Tests for “serving capacity” have been described for bulls.

The evaluation of semen quality is a major part of the breeding soundness examination. Semen from stallions is collected into an artificial vagina. Semen from ruminants may be collected into an artificial vagina or obtained by use of an electroejaculator. Semen collected by electroejaculation usually has a higher volume and a lower concentration of spermatozoa than semen collected by an artificial vagina. Semen quality in ruminants is scored primarily on the basis of motility and morphology.[7] Evaluation of semen from stallions should include determination of volume, concentration, motility, and morphology. The motility of the spermatozoa should be evaluated microscopically on raw and extended semen immediately after collection. In ruminants, bright-field microscopy at ×40 to ×125 magnification is used to detect mass motion or swirling to evaluate gross motility. Changes in sperm concentration, progressive motility, or speed of progression of spermatozoa will decrease or eliminate the swirling effect. Phase contrast microscopy at ×200 to ×500 is used to evaluate motility of individual spermatozoa. Computer-assisted semen analysis (CASA) has become more common in recent years to evaluate motility at larger reproduction facilities.

Concentration can be measured by use of a hemocytometer or a calibrated spectrophotometer. Morphology can be evaluated microscopically, using stained semen samples (e.g., eosin-nigrosin stain) or phase-contrast microscopy.

Ejaculates from stallions may be collected once daily for 5 to 10 days until daily sperm output (DSO) is achieved to fully evaluate potential fertility.[17] However, this is time-consuming, labor-intensive, and expensive. Consequently, most stallions are evaluated by the collection of two ejaculates 1 hour apart, with the total number of progressively motile, morphologically normal spermatozoa in the second ejaculate most critically evaluated.

The age of the stallion or male ruminant being evaluated for potential fertility may influence the semen parameters, measurements of the testicular size, mating ability, and libido. Puberty is attained in the male equine at 18 months, in the bull at 9 to 12 months, and in the ram and buck at 7 to 8 months.[18] Semen parameters and testicular size continue to increase until sexual maturity is reached. The season of the year in which the fertility evaluation is done may affect semen parameters in the stallion, ram, and buck.

Microbiologic samples should be routinely collected when evaluating infertility in the stallion and when evaluating high-risk populations of bulls. Smegma samples should be collected from the prepuce of bulls and cultured for *Trichomonas foetus* and *Campylobacter fetus*. Swabs from the preejaculate and postejaculate urethra, semen, and fossa glandis of stallions should be cultured for potentially pathogenic bacterial organisms, especially *Taylorella equigenitalis, Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*.[9] The semen of rams should be cultured for *B. ovis, A. seminis*, and *H. ovis*.[8,12,14] Serologic testing for exposure to equine arteritis virus (EAV), the causative agent of equine viral arteritis (EVA), is important for breeding stallions. In many states, determination of negative serologic status is required before vaccination against the virus may be performed.

Other tests that are occasionally performed to evaluate male reproductive function, health, or pathology include hormone analysis, chemical evaluation of seminal plasma, transmission electron microscopy of semen, karyotype, sperm chromatin structure assay, urethral endoscopy (stallion), and testicular biopsy.

After summarizing the results of the entire breeding soundness evaluation, stallions and male ruminants may be categorized into classifications, such as satisfactory, questionable, or unsatisfactory. In bulls a fourth category of "decision deferred" may be used for young prepubertal bulls or mature bulls that have recently experienced a transient disturbance in spermatogenesis. 197 198

It must be emphasized that the breeding soundness examination is a measure of potential fertility.[19] True fertility can be determined only by the results of breeding trials or by conception and live birthrates in dams bred.

12.2 CYCLIC IRREGULARITY

Steven D. Van Camp

Cyclic irregularity refers to an abnormal interval from the first day of estrus until the first day of the subsequent estrus. The alteration in the cycle length may occur during estrus or during the interestrous interval. Irregular cycles may be related to erroneous estrous detection, seasonal transitions, corpus luteum life span alterations, ovulation derangements, embryo or fetal wastage, or behavioral aberrations. In some cases the cause of the cyclic irregularity is unknown.

Inaccurate heat detection may appear as irregular cycles. Missed heats should be expected if the heat intervals approximate multiples of the normal cycle length (e.g., 42 or 63 days in the cow or mare). Silent heats (no clinical signs of estrus) were found to occur less often than suspected when cows were observed 24 hours a day, although silent heats do sometimes occur. The first ovulation of the season (ewe and doe) and the initial postpartum ovulation in cows usually are silent. Subestrum, weak, or short heats occur more commonly in the early postpartum period in the cow and may be caused by insufficient progesterone priming of the behavior center for optimum expression of estrus.[20]

Artificial insemination records may indicate that breedings are grouped so that two or more cows are bred the same day. This may indicate a failure to determine which animal is actually in heat. Short cycles may also indicate a lack of discrimination between the riding cow and the cow in standing heat. This type of error in estrous detection often results in the same cows being rebred within 3 days.

Anestrus is a particularly important type of cyclic irregularity with several causes. It is dealt with in a separate section of this chapter.

Nymphomania, a state of persistent or frequent heats, is the antithesis of anestrus. Many mares thought to be nymphomaniacal are actually exhibiting some degree of virilism. Frequently their ovaries are small and firm and appear inactive. These mares may actually be aggressive toward the stallion instead of receptive.[21] The cause of this condition may be behavioral rather than endocrine, as previously believed. Passive acceptance of the male, as can be seen in gonadal dysgenesis mares, can be mistaken for nymphomania. Mares with these chromosomal aberrations may accept service by the male, but they do not show the characteristic signs of estrous behavior in his presence. Nymphomania may be seen in cases of hormone-secreting granulosa cell tumors. Nymphomania also may indicate an ovulatory anomaly. Nymphomania in cows and goats is most often associated with ovarian follicular cysts. In ruminants, luteinized cysts, which cause anestrus, are more common.

12.2.1 Mechanisms of Irregular Cycles

Cyclic derangements occur either during estrus or in the interestrous interval. A delay in follicular maturation or ovulation may result in a prolonged proestrus or persistent estrus. This is seen in mares entering or leaving the physiologic breeding season in the transition from or to winter anestrus. It is likely the result of changing patterns of hypothalamic releasing factor and pituitary gonadotropin secretion.[22] Ovarian insensitivity to these substances may also play a role. The tubular tract may be insensitive to the ovarian hormones and may be atypical for the structures present on the ovaries.[23] The estrual behavior and ovarian structures may not correlate in these mares. They may have large follicles without heat or may show heat without large follicles being present. This may be a result of changes in the central nervous system's response to the sex steroids during the transition season.

Failure of ovulation can result in prolonged estrus. Mares frequently form persistent follicles during the transitional seasons. These usually regress with time and are not a long-term cause of infertility.[24] Ovulation failure can result in the development of follicular cysts and frequent or persistent heats in cattle.[25]

Other ovulation irregularities include delayed ovulation and premature ovulation. Delayed ovulation rarely occurs in animals. What may appear to be delayed ovulation is often erroneous heat detection or premature breeding. Similarly, premature ovulation is often misdiagnosed because of inaccurate heat detection. Premature ovulation may be suspected in heat-stressed animals that only show heat for short periods at the peak of estrus, or during the cool of the night.[26]

The mare seems to have a unique type of ovulation anomaly. After having one or more normal cycles, mares may spontaneously have a fertile, diestrous ovulation without signs of estrus. If the new corpus luteum develops after day 10 of diestrus, it has not had time to mature and become sensitive to prostaglandin-induced lysis. Thus the mare skips the next expected estrus and has a prolonged diestrus.[24]

The corpus luteum controls the length of diestrus and the interestrous interval in cycling animals. Premature lysis of the corpus luteum results in a short interestrous interval. If prostaglandin-induced lysis of the corpus luteum is prevented, the corpus luteum persists and a prolonged diestrus results.

Irritation or inflammation of the endometrium may cause premature release of prostaglandin and lysis of the mature corpus luteum, resulting in a short interestrous interval. Irritation of the endometrium late in diestrus may interfere with the action of prostaglandin on the mature corpus luteum, leading to a prolonged diestrus. Intrauterine therapy with irritating solutions may alter the interestrous interval, depending on when they are administered in the cycle. Treatment between 4 and 10 days after ovulation causes a short cycle in the cow.

Intrauterine treatment late in diestrus, 15 to 17 days after ovulation, results in a prolonged cycle, presumably because of a disruption of the synthesis or release of prostaglandin. In both cases the mare comes into heat 7 to 10 days after treatment.[27] Inadvertent intrauterine insemination during diestrus may induce a heat similar to that induced by infusion of other irritating solutions. Thus a split heat or short cycle may be seen.

Prolonged diestrus must be differentiated from early embryonic or fetal death. If embryonic death occurs after the time of maternal recognition of pregnancy (see the section Repeat Breeder), the next heat is skipped and the female returns to heat after a prolonged diestrus. This may last several months in the mare if the fetus is lost after the endometrial cups begin secreting equine chorionic gonadotropin (ECG; see the section Anestrus).

Diseases that cause endometritis may cause cyclic irregularity by two mechanisms. Endometritis results in premature lysis of the corpus luteum, leading to a short cycle. Endometritis also may result in early embryonic death (EED), which may culminate in a prolonged diestrus. Some viral agents, including some modified live vaccine strains, may attack the ovary and corpus luteum directly. The resulting oophoritis can lead to necrosis of the corpus luteum; therefore vaccination around the time of breeding is contraindicated.[28–30] These agents may also cause embryonic death, leading to apparent cyclic irregularity.[30–32]

198

199

12.2.2 Approach to Diagnosis of Irregular Cycles

Clinical evaluation of a case of cyclic irregularity requires a detailed reproductive history, more so than with many other reproductive problems. Examination of breeding records is essential. In dairy cows, errors in estrous detection are indicated when (1) more than 10% of the interestrous intervals are 3 to 17 days or 25 to 35 days long; (2) more than 5% of the cows have two artificial inseminations within 3 days; or (3) cows are calving early or are further in gestation than predicted from the last breeding when examined for pregnancy. Seventy percent of cows should have an interestrous interval of less than 30 days, and 60% should be in the range of 18 to 24 days. The ratio of 18-to-24—day cycles to 38-to-46—day cycles should be 5:1. Evaluation of heat-detection methods is important when dealing with a hand mating or artificial insemination program. Discussing the owner's understanding of the normal reproductive physiology of the species often is enlightening, and client education may be required. Observation of the teasing behavior of the animal is helpful, and examination of the reproductive tract should provide valuable information. Ancillary procedures such as ultrasonography, uterine culture, cytologic studies, and endometrial biopsy are often needed. Prediction of estrus through rectal examination or determination of the progesterone concentration (or both) may help. Progesterone determination on a sample collected at the time of insemination can be useful in evaluating the accuracy of heat detection. With ruminants it may be wise to suggest the use of a teaser, or marker male. Heat-detection aids (e.g., Kmar patches, tail chalk) are effective if applied properly and observed regularly. Serologic and microbiologic evaluation for the diseases known to cause endometritis or EED may need to be done if the source of the problem has not been determined.

Problems with cyclic irregularity can be difficult to decipher (Boxes 12-4 and 12-5). Management plays a large part, and it often is difficult to convince the client of this.

12.3 ANESTRUS

Steven D. Van Camp

Anestrus, the lack of ovarian activity, is a sign, not a disease. It may be a normal physiologic phenomenon or a sign of disease. Incorrectly perceived anestrous behavior may be an indication of inefficient heat detection. In adult

animals, pregnancy is the most common differential diagnosis of anestrus and should be ruled out before proceeding with diagnostic tests. Other differential diagnoses are those associated with an active corpus luteum and elevated progesterone levels, and those associated with low progesterone levels and the absence of an active corpus luteum.[33] Sequential ovarian palpations or determinations of the progesterone concentration can be helpful in determining the cause (Boxes 12-6 and 12-7).

12.3.1

Differential Diagnoses and Causes of Anestrus

1 *Pregnancy*. In any animal presented for anestrous behavior, the most important differential diagnosis to rule out is pregnancy. Any invasive diagnostic techniques must be reserved until after pregnancy has been ruled out. Many practitioners have experienced a case in which the history taken from the owner would make pregnancy seem an impossibility and then been surprised to find a healthy fetus.

2 *Inadequate heat detection*. In nonpregnant, hand-bred, or artificially inseminated animals, the intensity of estrous behavior may be diminished by environmental factors such as high ambient temperature and humidity or poor footing in the paddock. Clinical disease, such as musculoskeletal pain, may also prevent the normal expression of estrual behavior. Too few cycling herdmates may limit the ability to detect cows in heat.

3 *Psychologic problems*. Nervous mares, mares with foals, or dominant, fat, or phlegmatic mares experiencing normal estrous cycles may be reluctant to show estrus. Vigorous teasing with an aggressive stallion may be necessary to elicit estrous behavior in these animals.[34] Sequential ovarian palpations or

determinations of the progesterone concentration (or both) may be useful for predicting the next estrous period.

4 *Energy deficiency*. Inadequate prepartum nutrition or insufficient energy in the ration during lactation in dairy cattle and in postpartum beef cattle nursing a calf can delay the return to estrus after parturition.[35]

5 *Photoperiod*. Photoperiod plays an important role in the cyclic patterns of seasonal breeders such as the mare, ewe, and doe. The mare is a long-day breeder and has a normal anestrous period during the late fall and winter months. A mare that foals early in the year, during the late winter months (e.g., January through March in the northern hemisphere), and has not been kept under artificial lights during the 2 months previous to her foaling date is very likely to revert back into seasonal anestrus after her foal heat. The mare will remain in anestrus until April or May, when natural lighting conditions have been sufficient to stimulate her through the vernal transitional period and into normal cyclicity. The ewe and doe are short-day breeders and are normally anestrous in the spring and early summer, although breed variations occur.[36] Some sheep and goats near the equator have cycles throughout the year, presumably because of the consistency of the photoperiod.[37] The cow is not considered a seasonal breeder, but an increased photoperiod (18 hours of light to 6 hours of dark) has been shown to shorten postpartum anestrus in winter-calving beef cows.

6 *Hypothalamic or pituitary suppression or lack of stimulation.* Poor nutrition, heavy lactation, periparturient disease, hormone-secreting ovarian tumors, weight loss, or inanition associated with chronic disease may prevent stimulation of the pituitary by gonadotropin-releasing hormone (GnRH) from the hypothalamus.[34] Thus the pituitary does not release enough follicle-stimulating hormone (FSH) and luteinizing hormone (LH) for folliculogenesis, estrogen production, and ovulation by the ovaries. The inactive ovaries produce inadequate estrogen to cause behavioral estrus.

200 201

7 *Congenital or hereditary anomalies, including freemartinism in the cow and doe, intersex conditions that occur in polled goats, and gonadal dysgenesis in the mare*. The ovaries of these animals are unable to respond to FSH and LH stimulation from the pituitary. These animals frequently have rudimentary or hypoplastic ovaries and never display estrus.[38]

8 *Abnormal progesterone levels*. Inadequate progesterone exposure of the pituitary or hypothalamus before the first cycle of the season (ewe and doe) or the first postpartum estrus (cow) usually results in a silent heat.[35,39] On the other hand, suppression of the pituitary, the hypothalamus, or both by a high progesterone level can result in ovarian acyclicity or masking of behavioral estrus, or both.

9 *Retained or persistent corpora lutea*. These can occur spontaneously in the mare without evidence of a uterine pathologic condition. The mare is disposed to diestrous ovulations without estrus and the formation of corpora lutea that mask the next expected estrus. These previously cycling mares often demonstrate anestrus of several months' duration during the breeding season.[38] Persistent corpora lutea in the mare may also occur after fetal death while the endometrial cups are still producing ECG. These mares often undergo a 1- to 4-month anestrous period. Corpus luteum persistence can occur when the production or release of the luteolysin prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) is prevented. Segmental aplasia of a major portion of a uterine horn may prevent $PGF_{2\alpha}$ from acting on the ipsilateral ovary of the ruminant and may result in corpus luteum persistence.[33]

10 *Fluid, foreign bodies, or pathologic material in the uterine lumen*. Mucometra, hydrometra, and pyometra prevent the release of $PGF_{2\alpha}$ in ruminants.[33] Thus the corpus luteum persists, and perceived anestrus results. Pyometra in the mare may result in anestrus if the endometrial damage is severe enough to prevent production of $PGF_{2\alpha}$.[38] The presence of a mummified or macerated fetus in the ruminant uterus prevents release of $PGF_{2\alpha}$ and results in a persistent corpus luteum and perceived anestrus.[33]

12.3.2 Approach to Diagnosis of Anestrus

Knowledge of the reproductive physiology of the species involved is essential to understanding the cause of anestrus. Determining the cause of anestrus relies on an in-depth general and reproductive history, a thorough physical examination, and evaluation of the estrous detection programs involved. Pregnancy must be ruled out when dealing with any case of anestrus. In dairies using Dairy Herd Improvement Association (DHIA) records, inadequate heat detection must be suspected if the cows are determined to be cycling by palpation or progesterone tests but fewer than 50% of the possible estrous periods are detected; fewer than 70% of the cows are seen to be in heat by 60 days postpartum; and the average number of days to first service is over 80. The reproductive tract of the nonpregnant anestrous animal must be evaluated for any pathologic condition that might prevent estrus. The uterus of the ruminant should be evaluated for the presence of fluid, a macerated or mummified fetus, or a foreign body. Ultrasonography or radiology may aid the diagnosis of these conditions in small ruminants. The ovaries should be evaluated for luteal cysts (ruminants) or neoplasia. Ultrasonography and hormone concentration determination are often helpful if rectal palpation of the ovaries is impossible. If the ovaries appear to be normal in size, an attempt should be made to determine the presence of a functional corpus luteum producing progesterone. On-site milk or serum progesterone test kits are available for mares and ruminants. Sequential tests at weekly intervals may prove helpful in eliminating inadequate estrous detection as the source of the complaint of anestrus.

Some of the DHIA reproductive parameters can be used to assess the efficiency of estrous detection. The percentage of cows in heat by 60 days after parturition, the percentage of cows bred by 90 days after parturition, and the average number of days to first breeding can be used to evaluate the accuracy of heat detection if most cows have been determined to have normal, cycling reproductive tracts.[40] In addition, a 24-day heat-detection trial can be conducted. Of the nonpregnant, cycling cows, 80% to 85% should be found to be in heat within a 24-day period if estrous detection is adequate.

Anestrus is a frequent reproductive complaint. Often a number of causes are involved in a herd problem. The three most important differential diagnoses of anestrus in a herd are pregnancy, poor estrous detection, and inadequate nutrition. Concurrent, nonreproductive disease must be kept in mind when an individual anestric animal is examined.

12.4 REPEAT BREEDER

Steven D. Van Camp

Bruce W. Christensen

Managing repeat breeders is often frustrating and expensive. The repeat breeder is an animal that has been bred during three or more successive heat periods without being diagnosed pregnant.[41] An incidence of 10% to 15% repeat breeders is considered acceptable for dairies.[42] The incidence increases with the herd size and the level of milk production and with the use of artificial insemination.[43] This may be an even greater problem in the horse because 5% to 8% of mares lose their pregnancy in the first 4 months of gestation.[43] The use of ultrasonography and embryo collection indicates that the incidence of EED in the mare is likely even higher.[44] The syndrome of repeat breeders in mares is completely different from that in cows. In mares it is often associated with breeding-induced persistent endometritis. This is discussed in detail in Chapter 43.

The causes of repeat breeding are numerous and are related to male, female, and management factors (Boxes 12-8 and 12-9). The pathogenesis of repeat breeding involves either a failure of fertilization or EED.[42] Some etiologies, such as heat stress in the herd, may involve both mechanisms. Fertilization rates are normal in heat-stressed cows that are bred artificially, but heat stress increases the rate of EED. Heat stress can cause failure of fertilization by affecting spermatogenesis in males used in a natural breeding program.[45] When dealing with an individual repeat breeder, it is often wise to begin with the female. When several females are affected, the male should be eliminated as a source of the problem before proceeding. Management errors may be related to either male or female factors.

Fertilization failure is often the cause of repeat breeder syndrome. Studies have demonstrated delayed or inadequate release of LH, and consequent delayed ovulation, in repeat breeder cows compared with those cows showing normal fertility rates.[47] This observation has led to the investigation of GnRH (or its analogues) and prostaglandins as treatment options for repeat breeders, with some success.[48,49] In addition to LH abnormalities, repeat breeder cows showed prolonged duration of estrus, prolonged lifespan of the preovulatory follicle, and a late postovulatory rise in progesterone.[47] These changes negatively contribute to final oocyte maturation and competence in repeat breeder cows compared with unaffected cows.[50] Insulin has been shown to be an important mediator of follicular development, steroidogenesis, oocyte maturation, and subsequent embryo development,[51] and treatment with insulin has been shown to increase fertility in repeat breeder cows.[52] Workers in Japan have linked the repeat

breeder syndrome with abnormal profiles of endometrial epidermal growth factor (EGF). Assays of EGF have been suggested as diagnostic tools, and EGF treatment has been suggested to restore fertility.[53,54]

Early embryonic death also contributes as a cause of infertility in repeat breeders.[42,44] The interval between heats may help distinguish between EED and failure of fertilization. Failure of fertilization usually does not affect the interestrous interval. However, EED may prolong the interestrous interval if the fetal wastage occurs after the time of maternal recognition of pregnancy. Maternal recognition of pregnancy occurs at approximately days 15 to 17 after estrus in the cow, days 11 to 14 in the mare, and days 12 to 13 in the ewe.[55] Animals experiencing EED after pregnancy recognition often have interestrous intervals corresponding to multiples of a normal cycle length. Luteal insufficiency is suspected to cause EED in some repeat breeder cows, and trials of exogenous progesterone supplementation have shown promise for maintaining pregnancy in young late lactation repeat breeders.[56]

12.4.3 Approach to Diagnosis

Clinical differentiation of EED from failure of fertilization is difficult. In addition to evaluation of heat detection and breeding techniques, it is important to obtain a detailed history. When dealing with a herd problem, the clinician begins by evaluating the male or males used or assessing the semen quality and techniques used for artificial insemination. When dealing with an individual repeat breeder, evaluation of the female is the first step.

Evaluation of the male should include evaluation of the animal's physical condition, including the genitalia. The quality of the semen should be checked. The male's libido and ability to mount should be determined by observation or through historic information. Examination of the male for venereally transmitted diseases, such as trichomoniasis and campylobacteriosis in the bull and contagious equine metritis in the stallion, may be

warranted if other factors are ruled out. When dealing with an artificial insemination program, the semen quality should be evaluated and the thawing, transporting, timing, and deposition techniques should be evaluated.

Errors in heat detection and the timing of breeding are major management causes of repeat breeding. Discussing and observing the methods used to determine when an animal should be bred are important in dealing with both the individual animal and the herd. Milk or serum progesterone determinations at the time of breeding have proved helpful in determining the accuracy of heat detection and timing of insemination. In some dairies 40% to 50% of the cows are bred at the wrong time.

Examination of the female or females should begin with evaluation of the body condition. Poor nutrition has been associated with repeat breeding.[57] The reproductive examination should include evaluation of the vulva, vagina, cervix, uterus, oviducts, and ovaries. Poor vulvar conformation may lead to pneumovagina and endometritis, resulting in EED. The spermicidal effect of urine may cause failure of fertilization in the mare or cow that pools urine in the vagina. Cervical canal occlusion can prevent fertilization. An abnormal uterine environment may also lead to repeat breeding. Large volumes of pus and debris associated with a postpartum metritis may cause failure of fertilization because of its effect on sperm. Endometritis with minimal intraluminal pus rarely causes failure of fertilization but often results in EED. Unlike ruminants, the mare may continue to display estrus while experiencing pyometra. The volume of pus present in the uterus is likely to cause failure of fertilization. Hydrosalpinx or salpingitis may lead to failure of fertilization by blocking sperm or ovum passage. Ovulation abnormalities such as delayed ovulation or ovarian cyst formation may result in failure of fertilization. Whenever possible, including a uterine culture, cytologic smear, and endometrial biopsy as part of the examination is likely to help determine the cause of the infertility.

Differentiation of EED from failure of fertilization in repeat breeders has been facilitated by the use of embryo flushing techniques and ultrasonography. Collection of unfertilized ova indicates failure of fertilization; collection of degenerating embryos indicates very early embryonic death. In ruminants, failure to collect ova or embryos may indicate oviductal blockage resulting in failure of fertilization. This is not the case for mares because they usually retain unfertilized ova in the oviducts.

Ultrasonic determination of pregnancy in the mare and cow has made very early detection of pregnancy possible. Loss of an embryo after detecting it with ultrasound at 10 days of gestation confirms EED. Pregnancy wastage can be confirmed later in gestation with sequential rectal palpations of the reproductive tract or ultrasonic evaluation. Hormone assays are also helpful for confirming embryo or fetal loss.

An assay for ECG, previously called *pregnant mare serum gonadotropin* (PMSG), can be used to determine if a mare was pregnant long enough to stimulate formation of the endometrial cups and ECG production. ECG can be detected at about 40 days of gestation with these kits. The endometrial cups continue to produce ECG until 120 to 150 days of gestation even if the fetus dies. Therefore ECG can be used to confirm EED but not failure of fertilization. Progesterone determination cannot be used to confirm pregnancy in the mare or ruminants. However, it can be used to confirm nonpregnancy if the progesterone level is low early in the expected gestation. A bovine early conception factor test can be used to confirm fertilization, but it does not rule out EED later.

The fetally derived hormone-metabolite estrone sulfate has been used to determine the presence of a live fetus. It is detectable in the serum or urine of the dam if the fetus is alive after 45 days of gestation in the doe, 70 days of gestation in the ewe, 100 days of gestation in the mare, and 120 days of gestation in the cow.[58,59] Thus a decline in estrone sulfate indicates death of the fetus. Estrone sulfate is probably most helpful in confirming fetal loss in the doe and ewe because other techniques are available in the larger species.

Infertility associated with repeat breeding is a perplexing clinical problem. The economics involved often do not warrant pursuing the cause. If the cause is determined, therapy often is unrewarding.

Boxes 12-8 and 12-9 list the causes of repeat breeding in mares and ruminants. The causes have been divided into expected frequencies of occurrence.

12.5 PREGNANCY LOSS

Patrick M. McCue

Mats H.T. Troedsson

Pregnancy loss refers to the failure of a conceptus to be maintained successfully to term. Pregnancy loss may be classified as early embryonic death (EED), abortion, or stillbirth, depending on the gestational stage when the pregnancy loss occurred. EED is the death of a conceptus before organogenesis is complete (approximately 55 days in horses, 45 days in cattle, and 34 days in sheep).[60] *Abortion* refers to pregnancy loss after the completion of organogenesis. *Stillbirth* refers to the delivery of a nonviable fetus at or near term.

203 204

12.5.1 Early Embryonic Death

The exact incidence of EED in any species is difficult to determine because most losses occur before pregnancy can be routinely diagnosed. Embryonic death early in pregnancy usually results in reabsorption of the embryonic tissues and fluids. Consequently, EED cannot be distinguished from failure of fertilization in most instances. However, despite the lack of clinical evidence, EED probably accounts for the largest percentage of reproductive wastage in large animals. The incidence of EED has been estimated at 5% to 24% in mares,[61] 30% to 35% in cows,[62] and 20% to 30% in ewes.[63] The rate of EED is much higher in subfertile or repeat breeder females and in older females.

Loss of the embryo before maternal endocrine recognition of the pregnancy (i.e., days 14 to 16 in the mare, days 15 to 17 in the cow, and day 12 in the ewe and doe) results in return to estrus at the normal time. Embryonic loss after this critical period may result in persistence of the corpus luteum in horses, pseudopregnancy in goats, or irregular returns to estrus in cattle.

Chromosomal and genetic defects of the oocyte, sperm, or embryo; a poor oviductal or uterine environment; endocrine dysfunction; and maternal stress are all considered important factors in the pathogenesis of EED.[61,64] Infectious agents such as *T. foetus* and *C. fetus* subsp. *venerealis* in cattle[64] and *Streptococcus zooepidemicus* and other bacteria in horses[65] can cause EED. Endogenous release of $PGF_{2\alpha}$ during the corpus luteum—dependent stage of gestation may result in luteolysis and subsequent embryonic loss or abortion in any large animal species. Luteal insufficiency associated with low plasma progesterone concentrations has been suggested as a possible cause of EED in horses, cattle, and sheep, although scientific evidence is limited.[62,66,67]

12.5.2 Abortion

The rate of abortion after pregnancy diagnosis at 60 days of gestation has been estimated to be approximately 10% in horses[68] and 3% to 4% in cattle.[69] Fetal death may result in abortion (expulsion of the fetus from the

uterus) or retention of the fetus in the uterine lumen, with subsequent fetal maceration or mummification. In animals with a corpus luteum—dependent pregnancy for all or most of gestation (cows, goats, llamas), death of the fetus usually results in the abortion of an autolyzed fetus because of a delay between the time of fetal death and lysis of the corpus luteum. In species that do not depend on a corpus luteum for maintenance of pregnancy for most of gestation (e.g., mares and ewes), fetal death causes an immediate decrease in placental progesterone production and rapid expulsion of a relatively nonautolyzed fetus. Mummification is characterized by fluid reabsorption from a fetus retained in a sterile uterine environment. Fetal mummification is most common in multiparous species with a corpus luteum—dependent pregnancy (e.g., sows) and is rare in uniparous species that are corpus luteum independent for most of gestation (e.g., mares). *Maceration* refers to the degenerative changes that occur in a fetus after retention in a nonsterile uterine environment. Fetal maceration may be associated with significant maternal endometrial damage.

12.5.2.1

HORSES

Equine abortions may be characterized as infectious or noninfectious in origin. Most equine abortions occur secondary to placental dysfunction. One of the most commonly diagnosed infectious causes of abortion in horses is equine herpesvirus type 1 (EHV-1).[68] Abortion caused by EHV-1 usually occurs after 7 months of gestation and accounts for 10% to 15% of all diagnosed equine abortions. Exposure of pregnant mares to EAV may lead to abortion within 1 to 3 weeks after initial viral exposure. Abortion may be caused by vasculitis, edema, and necrosis in the endometrium and allantochorion.[70] There is no evidence that exposure to EAV at breeding can cause a mare to abort later in gestation. Abortion rates may range from 10% to 70% during an outbreak.

Consumption of Eastern tent caterpillars (larva of *Malacosoma americanum*) by mares causes abortion after approximately 40 days of gestation. The syndrome has been named *mare reproductive loss syndrome* (MRLS). Pregnancy loss at 40 to 150 days of gestation is characterized by hyperechoic amniotic and allantoic fluids on ultrasonographic examination along with a dead or dying fetus.[71,72] Near-term abortions are characterized by histologic lesions in the placenta and umbilical cord. In many cases, endometrial cultures are positive for non—beta-hemolytic streptococci and *Actinobacillus* species. Diagnosis of MRLS is currently based on four variable factors: placental lesions, culture of characteristic bacteria from fetal tissues, conformation of increased caterpillar exposure, and diagnostic elimination of other known causes of abortion (John Roberts, personal communication). The microscopic lesions observed in natural late-term MRLS cases are primarily the result of host response to bacterial infection, with the primary isolates being non—beta-hemolytic streptococci and actinobacilli.

During an outbreak in central Kentucky in 2001 and 2002, a variety of nonspecific lesions were reported that included placental edema, fetal pneumonia, and hemorrhages in the heart and placenta. During this outbreak, inflammation of the umbilical cord (funisitis), specifically the amniotic segment, was observed in 78% of cases.[73] Funisitis was also observed in three cases necropsied during a 2006 Florida outbreak. The lesion is initiated as a suppurative to pyogranulomatous response between the outer circumferential stroma and the outer tunica adventitia of major umbilical vessels and progresses outward to involve or ulcerate the amniotic surface of the umbilical cord (John Roberts, personal communication). Other causes of equine abortion such as noninfectious umbilical cord lesions, leptospirosis, and EHV should be ruled out by appropriate diagnostic tests. In addition, if a horse farm encounters unilateral endophthalmitis or pericarditis in the general population, MRLS should be elevated as a differential diagnosis for unsolved abortions.[74,75]

Nocardioform actinomycete a filamentous, branching bacillus, has recently been identified as a significant cause of chronic placentitis and subsequent late-term abortion, stillbirth, and premature birth.[76] *Leptospira* species have also been identified as a significant cause of equine abortion in Kentucky.[77] Bacterial and fungal abortions in mares are primarily caused by infections that ascend through the cervix, causing placentitis and subsequent fetal infection. The bacterial organisms most commonly cultured from aborted fetuses include *Streptococcus* species, *Escherichia coli, Pseudomonas* species, *Klebsiella* species, and *Staphylococcus* species. The most frequently recovered fungi are *Aspergillus* species.

The most common noninfectious cause of equine abortion is twin pregnancy.[68] Inability of the uterus to support two fetuses to term because of insufficient placental support may result in abortion at any stage of gestation but is most common after 7 months. Early diagnosis of pregnancy using ultrasonography allows for highly successful manual reduction of one twin if done before day 16 of pregnancy. This technique has significantly reduced the incidence of abortion caused by twin pregnancies.

204

205

12.5.2.2

RUMINANTS

Infectious bovine rhinotracheitis—infectious pustular vulvovaginitis (IBR-IPV) virus and bovine virus diarrhea—mucosal disease (BVD-MD) virus are two of the most common viral causes of abortion in cattle.[78] Bacterial abortions caused by *Brucella abortus, Arcanobacterium (Actinomyces) pyogenes, Bacillus* species, *Listeria monocytogenes, E. coli, Leptospira* species, and *Pasteurella haemolytica* and fungal abortions caused by *Aspergillus* species and *Mucor* species usually result from hematogenous spread and localization in the placenta.[79] Protozoal abortion, caused by *Neospora* organisms, has recently been recognized as a significant cause of abortion in cattle worldwide.[80] Epizootic bovine abortion (EBA) is a common cause of third-trimester abortion in susceptible heifers and cows inhabiting the foothills of the Sierra Nevada mountain range of California, Nevada, and Oregon.[81] The vector for EBA is the argasid tick *(Ornithodoros coriaceus)*, but the causative agent has not been identified.

Campylobacteriosis (vibriosis), caused by *C. fetus* and *C. fetus* subsp. *jejuni*, and enzootic abortion of ewes caused by *C. psittaci* are the most common infectious causes of abortion in sheep.[82] They are characterized by abortion in the last 4 to 6 weeks of gestation, premature births, stillbirths, and birth of weak, infected lambs. *C. psittaci* is also the most common cause of infectious abortion in goats in the United States.[83]

Noninfectious causes of large animal abortion include genetic or chromosomal factors, maternal stress, inadequate nutrition, vitamin or mineral deficiencies, ingestion of poisonous plants or other toxins, hormonal factors, environmental factors, physical factors, and certain medications.

12.5.3 Approach to Diagnosis of Abortion

A definitive diagnosis is reached in 20% to 40% of bovine abortions,[60] 50% to 60% of equine abortions,[68] and 30% to 40% of sheep abortions.[84] The generally low diagnostic success is a result of the complexity of the condition (Boxes 12-10 and 12-11). Abortion involves disease in the maternal, placental, and fetal compartments individually or together, and all these compartments have to be examined thoroughly. In addition, a “triad” of

determinants for animal disease has to be considered: (1) the presence of a pathogenic organism, (2) the environment in which a host lives, and (3) the susceptibility of the host to the disease.[85] To enhance diagnostic success, information and samples must be collected from the fetus, placenta, dam, and herd. A thorough history should be obtained, including the gestational age of the fetus; reproductive, medical, and vaccination history of the dam and other individuals in the herd; previous abortions and diagnoses; new arrivals to the herd and contacts of the animal with other herds; potential causes of maternal stress; possible access to toxins and poisonous plants; and sources of water and nutrition.

A physical examination that includes all body systems should be performed on the dam. Samples should be collected from the vagina, uterus, or both for culture and cytologic studies. Examination of the reproductive system should include palpation or ultrasonography of the reproductive tract per rectum, speculum examination of the vagina, and digital examination of the cervix. Paired serum samples from the dam and other females in the herd (10 animals or 10% of the herd, whichever is greater) may also help demonstrate an immunologic response to an infectious agent. Maternal serologic testing is generally most useful if paired samples are submitted, combined with accurate information about the animal's vaccination history. However, postabortion titers from cows that aborted can be compared with titers from unaffected cows in the herd at a similar stage of lactation. Demonstration of a fourfold rise in titer between acute and convalescent serum samples suggests recent exposure to an agent, but the presence of antibodies does not necessarily indicate that the agent caused the abortion. An exception can be made for brucellosis and leptospirosis, for which a high titer from a single sample can be diagnostic.

For optimal diagnostic efficiency, the entire aborted fetus and placenta should be submitted to a diagnostic laboratory for necropsy. If this cannot be done, a prompt necropsy should be performed, and collections of fetal, placental, and maternal samples should be submitted to a diagnostic laboratory (Table 12-1).

A systematic necropsy must be performed on the aborted fetus. Fetal age and development may be assessed by measuring crown-rump length, hair patterns, and color. Meconium staining of the skin suggests uterine fetal distress. The condition of the fetus, including the degree of autolysis, should be noted. A careful examination for fetal anomalies (e.g., cerebellar hypoplasia, hydrocephalus, cleft palate, cardiac anomalies) should be performed. Histopathologic samples should be immersed in a volume of 10% buffered formalin (or Bouin fixative) equivalent to 10 times the volume of tissue. Samples for culture, virus isolation, and fluorescent antibody tests should be submitted on ice in separate sterile containers. A sample of abomasum and stomach contents should be aseptically collected for culture. Fetal heart blood or thoracic fluid may be collected for serologic evaluation. A late-term fetus is immunologically competent, and high titers may indicate activity of a pathogenic agent. Serologic testing of fetal fluids can be useful both in detecting a nonspecific active fetal immune response (total immunoglobulin [IgG]) and for titers against a specific antigen.

The fetal membranes should be examined for size, weight, degree of autolysis, condition, and completeness. 206

Samples of placental tissue, especially areas with lesions, should be collected for histologic examination, impression smears, bacterial culture, virus isolation, and fluorescent antibody tests. The equine placenta should be examined for integrity, lesions, and distribution of chorionic villi. The normal equine placenta is everted after expulsion, with the allantoic surface presented outward and chorioallantois ruptured at the site of the cervical star. Blood may be collected from the free end of the cord. The allantoic surface should be examined for abnormalities such as multiple allantoic pouches that may indicate compromised fetal circulation.[86] The chorionic surface of the placenta should be examined for lesions and distribution of chorionic villi. Areas of avillous chorion are normally observed in association with the cervical star, narrow folds over large vessels, and 207

areas opposing endometrial cups. Absence of chorionic villi over a circumscribed area is characteristic of twins and represents the region where two placentas were in contact. The region of the placenta adjacent to the cervix should be examined for loss of chorionic villi and the presence of inflammatory exudate, a hallmark of ascending infection.

Table 12-1 Tissue Samples to Be Submitted for Diagnosis of the Cause of Abortion

	Preservation Method	
Source	**Chilled or Frozen**	**Fixed***
Aborted fetus	Lung, liver, kidney, spleen, thymus, skeletal muscle, heart, heart blood, abomasum, and stomach contents	Lung, liver, kidney, spleen, thymus, skeletal muscle (diaphragm), heart, adrenal gland, lymph node, brain
Placenta	Allantochorion (ruminants: cotyledons and intercotyledonary areas), allantoamnion, amniotic fluid, cord blood	Allantochorion (ruminants: cotyledons and intercotyledonary areas), allantoamnion
Dam or herd	Paired serum samples, vaginal or uterine swabs	

* 10% Formalin or Bouin fixative should be used.

The cotyledons and intercotyledonary spaces of the ruminant placenta should be carefully examined for lesions. Autolytic changes of the placenta may be difficult to interpret. Some normal features of the bovine placenta must be kept in mind.[69] Amniotic plaques are present on the inner surface of the amnion and on the umbilical cord. They are most prominent at 3 to 7 months of gestation. Necrotic areas of the chorioallantois in the tips of the uterine horns are also normal and caused by insufficient vascularization to that area. Mineralization of the placenta is normal during the first months of gestation but may reflect placental injury associated with infection at the end of gestation.

All aborted fetuses and placental tissues should be handled with care, and tissues not submitted to a diagnostic laboratory should be burned or buried. Dams that have aborted should be isolated from the remainder of the herd.

12.6 FESCUE TOXICOSIS

James P. Brendemuehl

Tall fescue (*Festuca arundinacea* Schreb.) is a cool-season, seed-propagated, perennial grass that is grown in many regions of the United States. It is traditionally recognized to be the most widely grown pasture grass in the humid areas of the southeastern and northwestern United States. Recent surveys have demonstrated endophyte-infected forage in more than half of all forage samples tested in all geographic areas of the United States.[87,88] An endophytic fungus, *Neotyphodium coenophialum*, has been shown to be widely spread wherever tall fescue is grown.[88] Undesirable signs in animals grazing tall fescue have been associated with the presence of the asymptomatic fungal endophyte (also see Chapter 54).

12.6.1 Clinical Manifestations of Fescue Toxicosis

Agalactia or hypogalactia is the most commonly reported clinical sign in mares grazing endophyte-infected fescue.[89,90] Mares grazing endophyte-infected fescue show significantly lower prolactin concentrations than mares grazing endophyte-free forage. Hypoprolactinemia associated with endophyte ingestion would inhibit normal mammary development in the prepartum period. Prolactin concentrations increase in the immediate prepartum period in the mare and return to baseline levels several weeks postpartum. Episodic increases in prolactin associated with nursing by the foal suggest the requirement of prolactin to maintain lactogenesis.[91] Suppression of prolactin by ergopeptines during the prepartum period in the cow reduced milk yields but had no effect after lactogenesis had been established. Therefore it appears that the endophyte reduces milk yield postpartum because of reduced intake.

Calving rates are decreased by the presence of endophyte in tall fescue.[92] Ewes grazing endophyte-infected fescue demonstrated a prolonged interval to conception after introduction of the ram compared with ewes on endophyte-free pasture.[93] Necropsy results and time to return to estrus indicated embryonic mortality as a cause. Mares grazing endophyte-infected fescue demonstrated increased embryonic loss rates, prolonged luteal function, and decreased per-cycle pregnancy rates compared with mares grazing endophyte-free pastures.[94]

Puberty in heifers is delayed by grazing endophyte-infected tall fescue. Progesterone concentrations were additionally decreased in heifers grazing endophyte-infected fescue, indicating luteal function was impaired.[95] Altered luteal function caused by endophyte exposure could possibly affect cyclicity and reduce pregnancy maintenance.

Mares grazing endophyte-infected tall fescue demonstrate a significant incidence of prolonged gestation, agalactia, dystocia, poor foal viability, and retained and thickened placentas.[89,96] Foals born to mares grazing endophyte-infected tall fescue are typically weak at birth with characteristic signs of dysmaturity, including overgrown hooves, irregular dental eruption, lanugo, and flexor laxity. Foal weights are significantly greater in endophyte-exposed mares despite reduced muscle mass. At birth, concentrations of triiodothyronine, progestagens, adrenocorticotropic hormone, and cortisol were significantly lower in foals from mares grazing endophyte-infected fescue.[97]

Endocrine alterations in pregnant mares grazing endophyte-infected fescue are a depression in prolactin, [89,90,97,98] thyroxine,[99] progestogens,[89,97,98] and relaxin.[100] Progesterone concentrations did not differ in mares that experienced early embryonic death, indicating an effect of the endophyte other than impaired luteal function.[94] Total progestogen concentrations were reduced with endophyte exposure of pregnant mares only after day 300 of gestation.[101] Short-term exposure of late-gestation mares to endophyte-infected fescue results in significant decreases in prolactin and progestogens.[101] At birth, concentrations of total progestogens were significantly reduced in mare jugular, foal jugular, and umbilical artery plasma, indicating reduced fetal and placental progestogen synthesis.[97]

Placental alterations in mares associated with consuming endophyte-infected fescue include premature separation of the allantochorion, increased allantochorion weight and thickness, and retained placenta.[89,96,98] Transabdominal ultrasonography demonstrated a significant increase in uteroplacental thickness in endophyte-infected mares. However, this was not observed until an average of 8 hours before the onset of labor. Premature

separation of the allantochorion was detected in conjunction with the increase in placental thickness. Histologic evaluation of the allantochorion revealed a significant increase in the splanchnic mesoderm caused by edema.

12.6.2

Approach to Diagnosis of Fescue Toxicosis

Definitive diagnosis of fescue toxicosis involves identification of the causative endophytic fungus in forage or seed samples by microscopic examination (Boxes 12-12 and 12-13). Ergopeptine concentrations may additionally be determined by high-pressure liquid chromatography analysis or specific enzyme-linked immunosorbent assay (ELISA). A presumptive diagnosis of fescue toxicosis can be made in cattle based on expression of the characteristic clinical signs of hyperthermia, excessive salivation, long, rough hair coat, necrosis of the tail and ear tips, and fat necrosis in association with consuming fescue forage. Hypoprolactinemia is supportive of the diagnosis, but the assay is not commercially available.

A presumptive diagnosis of fescue toxicity in the pregnant mare is based on the observation of failure of normal mammary development for gestational stage. Prolongation of gestation is commonly reported as well. An accurate breeding history should include dates of breeding, dates of confirmed pregnancy diagnosis, and absence of parturition at the anticipated time. A history of recent exposure to fescue pasture or hay is supportive. In tall fescue-endemic areas, pastures that contain tall fescue grass should be considered infected with the endophyte unless specific testing has confirmed otherwise. Determination of total plasma progestogen concentrations is a sensitive indicator of endophyte exposure after 300 days of gestation.[101]

Management of a mare suspected of endophyte exposure should consist of removing the mare from the suspected pasture or hay source and maintaining the mare in a stall or dry lot under close observation. High-quality hay, preferably legume, should be provided. Because of the increased incidence of dystocia in mares grazing endophyte-infected tall fescue, close monitoring of the mare and attendance at parturition is critical to minimize risk to the mare and loss of the foal. Removal of mares from infected fescue by day 300 of gestation has been demonstrated to alleviate the toxic effects on the mare and foal. Removal after day 300 carries an increased risk of prolonged gestation, agalactia, dystocia, and neonatal death. Induction of parturition is not recommended because of the high incidence of fetal dysmaturity, fetal oversize, and failure of pelvic relaxation associated with endophyte exposure. Elective cesarean section deliveries of postdate gestation mares have resulted in significantly higher foal survival rates than spontaneous deliveries.

Where removal of pregnant mares from infected fescue is not practical or mares are inadvertently grazed on endophyte-infected fescue beyond the recommended stage of gestation for removal, pharmacologic intervention

is warranted. Several DA_2 dopamine receptor antagonists—perphenazine,[103] fluphenazine,[100] and domperidone[104]—and the dopamine depletor reserpine[105] have been investigated prophylactically to prevent or therapeutically to treat clinical fescue toxicosis. Perphenazine[103] and fluphenazine[100] have demonstrated mixed success in preventing toxicosis in restricted clinical trials. Reserpine[105] was ineffective in preventing prepartum agalactia and prolonged gestation but was sufficient to resolve postpartum agalactia. Domperidone[106] has demonstrated efficacy in both the prevention and treatment of clinical fescue toxicosis in clinical trials involving large numbers of mares in numerous locations.

209

12.7 PROLONGED GESTATION

Bruce W. Christensen

Many factors influence the duration of gestation in horses and ruminants. Normal variations in length of gestation have been attributed to genetic, nutritional, and environmental factors.[107,108] The species, breed, and sex of the fetus, ambient temperature, and length of photoperiod are among factors that, within normal variations, affect the duration of gestation.[107–110] The duration of pregnancy in thoroughbred mares ranges from 310 to 374 days,[110] in dairy cows from 275 to 292 days, in beef cows from 271 to 310 days, in ewes from 143 to 155 days, and in does from 146 to 155 days.[111] Prolonged gestation periods are those that exceed the normal gestational variation attributable to genetic, nutritional, and environmental factors. In pathologic prolonged gestation there is an impediment to the mechanisms that terminate gestation and initiate parturition. Pathologically prolonged gestation has been attributed to genetic, infectious, and toxic factors[112] as well as to manipulation of the embryo.[113,114]

Of the several forms of prolonged gestation with genetic causes in cattle, the best described forms have been observed in Guernsey and Holstein cattle.[108,109,112,115] In each the fetus fails to initiate parturition at term because of fetal adrenal hypoplasia. Prolonged gestation, from 3 weeks to 3 months beyond normal term, has been observed in a number of dairy cattle breeds.[116] Graves, Hansel, and Krook[115] described a Holstein fetus of 441 days' gestation in which the pituitary pars distalis was aplastic and the adrenal and thyroid glands were severely hypoplastic. Two different types of fetuses have been associated with prolonged gestation in cattle.[107] In the first type, fetuses had a large skeleton and excessive growth of epidermal organ structures such as hair and hooves but no obvious deformities. The second type of fetus was mature or immature and exhibited cranial and central nervous system anomalies; growth ceased at about 7 months of gestation. Both types of calves had hypoplastic or absent adrenal glands. These anomalies have been observed to be inherited as an autosomal recessive trait.[108,112]

Several infectious agents have been incriminated in prolonged gestation in ruminants. Bluetongue virus, bovine diarrhea virus, and border disease virus may cause severe cerebral lesions in the fetus, resulting in the absence of a hypothalamus and pituitary stalk. Again, by virtue of the lack of adrenocorticotropic hormone, the sequence of events necessary for parturition does not occur.[112]

The last decade has seen an increase in the use of assisted reproductive techniques in cattle in the form of in vitro procedures and somatic cell nuclear transfer (“cloning”). Although these techniques offer advantages for reproducing important genetic lines, they still have many accompanying complications that have yet to be overcome. Besides increased pregnancy loss, increased birthweight of calves, and increased incidence of dystocia and perinatal losses, another of these complications is prolonged gestation in recipient cows compared with embryo transfer recipient and artificially inseminated cows.[113] This technology has great potential for manipulating and preserving superior genetic potential.[117] The cow has been the most successfully cloned animal to date, but such

cloning still has a low success rate (0% to 10%).[118,119] This is an extremely active area of research and it is likely that with further understanding the current pitfalls surrounding in vitro procedures and nuclear transfer will be overcome and use of the techniques will become more commonplace.[119]

Veratrum californicum contains the teratogenic agent cyclopamine. When pregnant ewes ingest cyclopamine on the fourteenth day of gestation, their fetuses lack a pituitary gland or have a malformed hypothalamic stalk. These defects result in prolonged gestation by virtue of secondary adrenal hypoplasia.[112]

Prolonged gestation in mares has been cited as an indication for induction of parturition.[120,121] However, the clinical significance of prolonged gestation in mares is undetermined because there is no apparent correlation between duration of gestation and readiness for birth. Dysmature neonatal foals have resulted from gestations of normal and longer than normal durations; alternatively, 399 days' gestation resulted in births of normal twin foals.[122] Prolonged gestation in the mare has not generally been associated with excessively large foals and dystocia.[123] Therefore, in the absence of clinical signs that warrant induction of parturition in a high-risk pregnancy and the fulfillment of criteria for induced parturition, there is no reason to perform elective parturition induction in mares in which gestation is prolonged.

12.7.1

Approach to Diagnosis of Prolonged Gestation

Approach to the diagnosis of prolonged gestation in mares and ruminants is essentially similar (Boxes 12-14 and 12-15). If the client is concerned about what is apparently prolonged gestation in an otherwise normal dam, an accurate breeding history should be obtained. Because no pathognomonic clinical or laboratory findings are associated with prolonged gestation, the diagnosis is predicated on the history and a general physical examination of the dam. The overall condition of the dam should be determined. In addition to the reproductive history, exposure to infectious agents and toxic plants should be determined. The most important anamnestic factors are breeding dates, dates of confirmed pregnancy examinations, and absence of parturition at the expected time. The reproductive tract should be examined for the gravid uterus and evidence, although tenuous, of the term or near-term fetus. Diagnostic ultrasonography can be incorporated into the workup to enhance the assessment of viability and fetal well-being by determination of fetal heart rates, fetal size and movement, uteroplacental thickness, and estimation of allantoic fluid volume.[124–126] Parturition should not be induced unless the objective is fetal survival in the face of a high-risk pregnancy.[126] Otherwise, the mare should be examined and, if appropriate, the owner assured that the gestation is probably normal and that patience will likely result in a normal foal with adequate colostrum and passive immunity.[127]

12.8

DYSTOCIA

Mats H.T. Troedsson

Dystocia is defined as difficult parturition; it may be a sign of either maternal or fetal conditions that impede fetal passage through the birth canal.[128] Dystocia in mares and ruminants is more likely to be attributable to fetal causes such as malpresentation, malposition, and malposture than to maternal conditions[128,129] (Boxes 12-16 and 12-17). The overall incidence of dystocia and incidences of types of dystocia vary among the species and breeds within a species.[130] Cattle, especially first-calving heifers and larger breeds, are more commonly affected by dystocia; the overall incidence of bovine dystocia ranges from 3% to 25%.[128] The incidence of dystocia among thoroughbred mares is 4%,[129] and in does, 3% to 5%.[131] The incidence of dystocia is generally greater in sheep than in goats.[132] Dystocia represents an emergency situation that commands prompt resolution to afford the optimum prognosis for dam and fetus. Reposition, traction, fetotomy, and cesarean section are the obstetric procedures available for the management of dystocia.[133] The economics of large animal practice often play a significant role in determining which course to pursue in resolving dystocia. The lives of the dam and the fetus may be at risk. Although the objective should be the survival of both, unless otherwise advised by the owner and if conditions are not prohibitive, the well-being of the dam and her reproductive potential should have priority over the fetus.

Although parturition has been divided into three distinct stages for descriptive purposes, the stages overlap clinically, and normal parturition is observed as a continuous process.[129] The equine fetus is lying in a ventral or ventrolateral position with head and forelimbs flexed during late gestation.[134] During the first stage of parturition the fetus plays an active role, along with myometrial contractions, in assuming correct extremity posture as it positions itself for delivery through the birth canal. The second stage of parturition commences with rupture of the chorioallantois and culminates in delivery of the fetus. Myometrial contractions continue during third-stage parturition, which ends with the expulsion of the placenta. In the mare parturition is a forceful, explosive act. The time between rupture of the chorioallantoic membrane and delivery of the fetus is normally about 20 minutes.[128] Separation of the fetal membranes from the endometrium may occur within 1 to 2 hours after the second stage of parturition commences; therefore the retained fetus must be delivered quickly or it will asphyxiate. Fetal expulsion in the ruminant is not quite as explosive as in the mare; second-stage parturition in the bovine usually requires ½ hour to 4 hours.[128] Ewes and does require a range of ½ hour to 2 hours to complete the second stage, or slightly longer if twins or triplets are present.[128] Primiparous animals generally require a longer time to expel the fetus than do multiparous dams.

Dystocia in large animals is often accompanied by forceful straining. The dam may attempt to lie down and stand repeatedly. This is characteristic of dams with dystocia that is caused by fetopelvic disproportion, malposture, or fetal impaction. Alternatively, the dam may stand quietly with minimal or no straining, as in cases of uterine inertia, uterine rupture, or exhaustion associated with prolonged dystocia of any cause. Whatever the presentation of the dam, the attending veterinarian must be prepared for unexpected behavior when attempting to perform obstetric examinations and procedures. The dam, fetus, attendants, and veterinarians must be protected from injury. The dam should be placed in open-ended stocks with movable sides or a straw-bedded box stall. During obstetric examination and manipulation, mares and cows may attempt to get up and lie down, or they may suddenly collapse. Such sudden movements may injure the dam and veterinarian if rigid, closed-end stocks are used. Minimum physical restraint should be used; however, restraint should be sufficient to permit completion of the obstetric examination and procedures with efficiency and safety. General anesthesia followed by elevation of the hind quarter will facilitate safe manipulation and vaginal delivery of a foal in mares with dystocia. This technique, if applied correctly, will likely result in less damage to the mare's reproductive tract.

Little is known about the pharmacokinetics of drugs in pregnant domestic animals. Accordingly, it must be assumed that sedative and anesthetic drugs will depress neonatal and fetal functions at least as much as those of the mare. The effects on myometrial activity of drugs administered to dams experiencing dystocia must also be considered. Acepromazine has little effect on the fetus and is generally considered safe for use in the pregnant mare. However, acepromazine was shown to have a suppressive effect on myometrial activity in cycling mares.[135] Xylazine causes significant fetal cardiovascular compromise in horses and has been reported to stimulate myometrial activity in cows and mares.[135–137] The fetal and myometrial effects of detomidine are similar but of longer duration compared with those of xylazine.[135,136] The effects of detomidine on myoelectrical activity in the uteri of cows and mares treated during the last trimester of pregnancy were dose dependent.[138,139]

As equipment is being organized and the process of evaluating the dam begins, a pertinent reproductive history should be obtained, including the dam's age, her previous breeding history, and the outcomes of previous pregnancies (i.e., abortion, normal parturition, dystocia). Her present gestational status should be determined; has parturition commenced at term, or is it a preterm or postterm delivery? Her udder should be examined to determine the stage of development. Information about the progress of the current parturition should be obtained. The time

since rupture of the chorioallantoic membrane, the duration and intensity of labor, whether fetal membranes or parts have appeared at the vulva, and previous attempts to assist in delivery should be noted. If the dam is recumbent, the veterinarian should determine if she has attempted to or been able to rise. Although a complete examination of the dam is optimum, it should be postponed until after the delivery of the fetus. However, in obtaining the dam's reproductive history, questions about her current physical condition should be included. Such predisposing factors as recent weight loss, systemic disease, and trauma should be considered. She should be assessed for signs of hemorrhage, dehydration, and shock.

After the tail has been wrapped, the perineal area should be thoroughly and gently washed and rinsed. Examination of the dam's reproductive tract may cause some discomfort or pain. Temperance regarding analgesia and sedation must be practiced. Caudal epidural anesthesia (4 to 8 mL of 2% lidocaine or other anesthetic) is often an excellent means of facilitating examination and resolution of dystocia and at the same time minimizing trauma to the dam, fetus, and operator. Lidocaine epidural anesthesia may cause hindlimb weakness and ataxia. Safe and effective analgesia can also be induced by epidural administration of xylazine (0.17 mg/kg diluted in 10 mL physiologic saline). A combination of lidocaine (0.22 mg/kg) and xylazine (0.17 mg/kg) resulted in an onset of analgesia within a few minutes and a duration of over 5½ hours.[140] Although vaginal sensitivity and the Ferguson reflex both are reduced by epidural anesthesia, myometrial contractions and abdominal press are not totally eliminated. General anesthesia will effectively eliminate myometrial contractions and abdominal press. This approach has to be combined with an elevation of the hindquarter of the dam, in order to provide sufficient space for safe manipulation of the fetus. Great care must be taken during the examination of the genitalia and fetus. In addition to the viability of fetus and dam, the dam's future reproductive potential is at risk and must be preserved. The vulva, vestibule, vagina, and cervix should be carefully examined. The location of the fetus in the birth canal, as well as its viability, presentation, position, and posture, should be determined. Schuijt and Ball[141] described a procedure to manually dilate the bovine birth canal before forced extraction is attempted. In the management of dystocia in any species, forced extraction should proceed only after maximal dilation of the caudal reproductive tract in order to minimize the potential for injuries to the dam during parturition (i.e., cervical, vaginal, and vulvar lacerations, hematomas, postparturient vaginal necrosis, and obturator, perineal, and gluteal paralyses).[128,142] Mares are especially susceptible to cervical lacerations, which may have detrimental consequences on the dam's future reproductive performance. Slow traction with continuous palpation of cervical stretching by the attending obstetrician is therefore recommended in equine dystocias.

The integrity of the birth canal, fluids, and fetal membranes serves as an indicator of the length of time the dystocia has persisted and the well-being of the fetus. Generous lubrication is required in all cases of dystocia and should be applied continuously during the management of dystocia to prevent damage to the dam's birth canal. Lubricating preparations consisting of methyl cellulose are superior to those consisting of mineral oil or soaps. Several liters of lubricants should be infused into the bovine and equine uterus by the use of a nasogastric tube.

211 212

Traction or forced extraction can usually be successfully implemented after correction of malpresentation, malposition, or malposture. In equine dystocia, if the foal is still alive and dystocia cannot be relieved quickly (20 minutes) or if it is determined that extensive manipulation will be required, general anesthesia may be induced. Because of the length of the extremities of the foal, mutation is more difficult in the mare than in the cow and requires extensive repulsion to provide adequate room for manipulation. Examination and manipulation can be greatly facilitated by elevating the mare's hindquarters, enabling the fetus and viscera to recede cranially into the mare's abdominal cavity, thereby allowing more room for the operator.[143] If a nonviable fetus cannot be delivered by traction or forced extraction or if the owner is unwilling to select cesarean section, fetotomy can be performed.[133,143] Beyond the delivery of the nonviable fetus, fetotomy is indicated to save the mare and her subsequent fertility.[133] The advantages of fetotomy include avoiding major abdominal surgery (cesarean section) and its

complications and preserving the birth canal because excessively large parts are not forced through it.[128,142–144] At the same time, the primary disadvantage of fetotomy, particularly if not properly performed by an experienced obstetrician, is trauma to the birth canal by instruments, wire, or bone.[128] The indications, equipment, procedures, and complications of fetotomy have been reviewed in several publications.[128,133,142–144]

Cesarean section is indicated for a dam with dystocia when attempts to deliver the fetus by reposition, traction, and fetotomy are unsuccessful or contraindicated, and continued attempts may compromise the fetus, the dam, or her subsequent fertility.[128,130,132,145–152] Cesarean section may be the only rational procedure for delivery of some fetuses (e.g., emphysematous fetuses, deformed fetuses, and bicornuate fetuses). In addition, high-risk pregnancies caused by maternal conditions can be effectively and efficiently managed by cesarean section.[148] The specific indications, procedures, and complications of cesarean section have been reviewed in a number of publications.[128,130,145–152]

Management of a case of dystocia is not complete until a systematic examination, focusing on the dam's reproductive tract, has been conducted. Complications during dystocia involving the reproductive tract and other body systems can affect the outcome of the case.[128,153–155] As much as possible, examination of the dam's reproductive tract should rule out the presence of another fetus in the uterus or abdominal cavity.[128] The most common reproductive injuries incurred by dams during parturition include cervical, vaginal, and vulvar lacerations, hematomas, postparturient vaginal necrosis, and uterine hemorrhage.[142,155,156] Gastrointestinal complications, such as constipation associated with unwillingness to defecate, postpartum perineal inflammation, and bruising or rupture of entrapped or compressed segments of the gastrointestinal tract, can follow parturition in the mare.[155] Musculoskeletal and neurologic complications have been reported after parturition in cows and mares.[128] Retained placenta, delayed uterine involution, metritis, and laminitis may result from normal parturition but are more likely sequelae of dystocia.[128,155,157]

The signs associated with normal progression of each of the stages of parturition must be explained carefully to clients and farm managers. It is only through understanding the clinical signs associated with events of normal parturition that clients become proficient at recognizing abnormal events and know when to seek professional assistance.

12.9 RETAINED FETAL MEMBRANES

Mats H.T. Troedsson

Retained fetal membranes represent the failure of the entire or partial placenta to be expelled within physiologic time limits. Although variation exists among species regarding the duration of time that must pass before a placenta is considered retained, the condition is one of the most common complications occurring in animals after parturition.[158]

12.9.1 Retained Fetal Membranes in Mares

The anatomic structure of the equine placenta is described as diffuse, epitheliochorial, and microcotyledonary. It is composed of the allantochorion, the allantoamnion, and the umbilical cord.[159] During most normal foalings, the separation of fetal membranes from the endometrium and their subsequent expulsion occur within ½ hour to 3 hours of the delivery.[158] The incidence of retained fetal membranes is 2% to 10% in the mare, with a higher

incidence in draft horses than in lighter horse breeds.[158] The cause of retained fetal membranes remains unclear, but it is believed that allantochorionic microcotyledons near the tip of the nongravid uterine horn have failed to separate as a result of an endocrine unbalance, a disturbance in normal myometrial contractions, or any swelling at the site of microcotyledons[160] (Box 12-18). Diagnosis of retained fetal membranes in the mare is straightforward when it is based on the observation of membranes hanging from the vulva beyond 3 hours after foaling. However, if the fetal membranes fall cranially over the pelvis, they remain within the uterus without being visible, and the diagnosis must be made using vaginoscopy or ultrasonography or by digital intrauterine examination. If an early diagnosis of complete or partial retention of fetal membranes has been missed, the diagnosis may be made 1 to 2 days after foaling. At this time, clinical signs indicative of metritis are often present (i.e., fever, depression, colic, and/or laminitis).

After their expulsion, the fetal membranes should be stored until they can be scrutinized to determine if they are complete. The clinician should rinse the fetal membranes with water and, on a flat surface, thoroughly examine them for completeness.[161] Evidence that a part of the placenta is retained in the uterus or that an area of microvilli has been sheared off and retained in the endometrial crypts is an indication for digital endometrial examination or ultrasonographic examination, and institution of appropriate therapy (see Chapter 43, Retained Fetal Membranes).

12.9.2 Approach to Diagnosis of Retained Fetal Membranes in Mares

12.9.2.1 HISTORY

Many cases of retained fetal membranes follow episodes of dystocia, cesarean section, and fetotomy. An increased incidence of retained fetal membranes has been reported in mares that abort after the seventh month of gestation.[162] However, no increase in the incidence of retained fetal membranes associated with abortion, stillbirth, twinning, and delivery of a weak or diseased foal was observed if it occurred without dystocia.[163]

12.9.2.2 PHYSICAL EXAMINATION

Fetal membranes must be examined after their expulsion to determine their entirety and integrity. Tears, missing areas of tissue, and areas of chorionic surface devoid of microvilli should be considered evidence of partly retained fetal membranes, and immediate action should be taken to enhance expulsion of retained tissue and minimize complications.

Vital signs may be normal early in cases of retained fetal membranes. A rectal examination should be performed to determine the degree of uterine involution. Aseptic intrauterine palpation can be performed to determine the area and extent of retention and the integrity of involved tissues and fluid.[161] Systemic signs of dehydration, septicemia, toxemia, and laminitis may accompany fetal membranes retained for 24 to 36 hours.[164] Occasionally mares with retained fetal membranes show signs of colic. Therapeutic approaches for retained fetal membranes in mares are discussed in Chapter 43.

12.9.3

Retained Fetal Membranes in Ruminants

The anatomic structure of the ruminant placenta is described as cotyledonary and epitheliochorial.[158] It is composed of the allantochorion, the allantoamnion, and the umbilical cord. Fetal membranes are considered pathologically retained in the cow if they are not expelled by 8 to 12 hours after calving.[158] The incidence of retained fetal membranes in dairy cattle is 3% to 12% after normal parturition.[165] Dairy cows are more commonly affected than beef cows.[165] The incidence of retained fetal membranes may exceed 50% after abnormal parturition or abortion and in brucellosis-infected herds.[165] The retained placenta itself is relatively innocuous, but the condition is important because cows with retained fetal membranes experience an increased incidence of postpartum complications such as metritis, pyometra, ketosis, mastitis, delayed conception, and abortion.[166,167] The principal cause of retained placenta in cattle is a disturbance in the loosening process between the fetal cotyledons and the maternal caruncles[168] (Box 12-19). The processes that lead to successful loosening and separation of the placentome occur during the months preceding parturition. Many infectious and noninfectious factors are believed to disrupt the separation and expulsion processes. An endocrine causal relationship does not appear to exist.[169]

Clinical signs of retained fetal membranes in the doe and ewe are similar to those in the cow. The placenta of the ewe and doe is considered retained if it is not expelled within 24 hours after parturition.[170] The incidence of retained placentas in does is 6.4%.[171] Placental retention for longer than 24 hours may cause metritis in ewes and does. Inadequate dietary selenium and inadequate nutrition and exercise during gestation have been seen as factors predisposing does to retained placentas.[171] There have been several reports on factors that predispose to retained fetal membranes.[158,165–168,172,173] Many infectious and noninfectious factors apparently contribute to the disruption of the process of loosening and separation of the placentome. Accordingly, it has been suggested that a retained placenta should be considered to be a sign of an underlying disease.[174]

12.9.4 Approach to Diagnosis of Retained Fetal Membranes in Ruminants

12.9.4.1 HISTORY

A review of accurate breeding records correlates retention of fetal membranes with the duration of pregnancy. Gestational periods of abnormal lengths result in a higher incidence of retained placenta than do normal-term parturitions. Induced parturition, twinning, and late-term abortions have been associated with retained fetal membranes in cows. Many periparturient diseases and conditions affect the incidence of retained fetal membranes.[158,165–168,172,173]

12.9.4.2 PHYSICAL EXAMINATION

In cows that have calved spontaneously and without problem after a normal gestation period, little illness tends to be associated with retained fetal membranes, and treatment may be unnecessary. Transient decreases in appetite and milk production may be observed.[165] However, metritis, toxemia, and septicemia may be observed when retention of fetal membranes is associated with gestation of abnormal length, dystocia, nutritional deficiencies, or certain infectious diseases. Metritis affects up to 90% of cows with retained fetal membranes.[172] For considerations for the treatment of retained fetal membranes in cows, see Chapter 43.

12.10 ALTERATIONS IN LACTATION

Bruce W. Christensen

The mammary glands are modified cutaneous glandular structures considered accessory reproductive organs that function to secrete milk for the nourishment of the young.[175] The mammary glands are located in the prepubic region in the mare, cow, ewe, and doe. The cow's udder is composed of four mammary glands, whereas in the doe, ewe, and mare the udder has two mammary glands. One teat serves each mammary gland, and in the cow, ewe, and doe each teat has one streak canal. The mare has two streak canals per teat.

The mammary glands are ectodermal in origin, and most of their fetal development occurs during the first half of gestation.[176] Except for growth that occurs in association with some of the anomalous conditions of the mammary gland or as a result of the deposition of fat, there is little growth of mammary tissue between birth and puberty. Further mammary gland development occurs with each estrous cycle after the onset of puberty. Development of the duct system is primarily attributable to estrogen. Progesterone is the principal stimulant to development of secretory tissue. However, neither estrogen nor progesterone alone or in combination can cause optimum mammary gland growth and development.[177] Insulin, cortisol, thyroxine, prolactin, and growth hormone are necessary for full mammary gland development. During pregnancy the mammary gland attains maximum development under the control of pituitary, ovarian, adrenal, and placental hormones.[178] During parturition a process of interrelated neuroendocrine processes initiates lactogenesis, the production of milk. The secretion of milk and its release from the mammary gland after parturition depend on the availability of appropriate amounts of the hormones named previously, especially prolactin and oxytocin.

In addition to mastitis, conditions that manifest themselves as alterations in the mammary gland and lactation are fairly common in ruminants and horses. Problems caused by conditions that affect the mammary gland are often multifactorial in that they compromise the well-being of the patient, the nutrition of the offspring, and ultimately the economics, especially in commercial dairies.

12.10.1

Enlarged Mammary Gland

Many conditions and diseases of the mammary gland cause swelling or enlarging of the gland[179] (Boxes 12-20 and 12-21). Enlargement may involve one or more of the glands of the udder. However, the enlarged mammary gland is not necessarily inflamed. Several anomalies of the mammary gland cause noninflammatory enlargement of the gland (e.g., gynecomastia and precocious udder development).[179–181] It is important to determine whether the enlargement of the gland is attributable to an infectious or a noninfectious cause. Trauma is probably the most likely cause of noninfectious inflammation of the mammary gland. Mastitis, with which a large number of organisms have been associated, is the most common cause of mammary gland inflammation (see Chapter 36).

Evaluation of a patient with an enlarged mammary gland should include the medical and reproductive histories. The age and sex of the animal may limit the considerations. Gynecomastia is seen in young bucks, rarely in rams and bulls, and never in stallions.[179,181] Congenital anomalies such as stenotic or absent teat canals are not determined until parturition occurs and lactation commences.[179] The animal should be given a complete physical examination, with emphasis on the affected mammary gland. Examination of the gland should include observation, palpation, and expression of its contents. Cytologic and bacteriologic examination of the secretion from the mammary gland may be helpful in determining the cause and establishing the prognosis of enlarged mammary glands. In postpartum cows the most common causes of enlarged mammary glands are periparturient udder edema and mastitis. Mastitis occurs most often in mares after weaning. Trauma to the udder is more likely to be problematic in cows and goats than in ewes and mares because the udder is more pendulous in the former.[179] Undesirable udder traits of genetic origin occur in the goat (e.g., hanging or saclike udder, polythelia, and blocked teat).[182] Lacerations, superficial contusions, and seromas are detected by close examination of the affected gland. Diagnoses of other injuries may rely on examination of the gland's secretion for evidence of increased cellularity and hemorrhage. Mammary gland neoplasia is rare in mares, cows, and small ruminants.[179,183–185]

12.10.2 Udder Edema

Udder edema, one of the most common causes of enlarged mammary glands, results from the excessive accumulation of intercellular fluid in the mammary gland (Box 12-22). The disorder is observed during the late gestation and early postpartum periods and is common in both horses and ruminants, but it is probably more frequently seen in dairy cattle. One study reported an udder edema incidence of 18% in dairy cattle, of which less than 1% required veterinary treatment.[186]

Two forms of udder edema are seen in cattle.[187] In the physiologic or acute form, there is edema of the mammary gland during the late gestation and early postpartum periods.[187] The entire udder is usually symmetrically involved, and the edema may involve adjacent abdominal and perineal areas.[187] The condition is usually not obviously painful but may cause the cow some difficulty in lying down and walking because of the mammarian swelling. Chronic bovine udder edema differs from the acute form in that affected cows develop udder edema within 6 weeks after calving, and the edema may persist for several months.[187] The swelling may be localized in the form of plaques on the ventral aspect of the rear of the udder, or it may involve the ventral abdominal wall.[187]

Udder edema is a relatively common condition of dairy goats.[188] Two-year-old does kidding for the first time are most commonly affected; however, all ages can be affected. Affected does usually have colostrum at parturition, but within a few hours the udder is warm, hard, and agalactic.

Broodmares affected with udder edema have generalized ventral edema during the last 1 to 2 weeks of gestation and for as long as 2 to 3 days after foaling. The extent of ventral edema varies, ranging from local swelling of the udder and immediately adjacent subcutaneous tissues to a generalized swelling that may extend from posterior to the mammary glands forward, along the ventral abdomen and thorax, to the axillary or pectoral area. In the mare such edematous accumulations are referred to as *plaques of edema*. Affected brood mares seem to be uncomfortable and reluctant to move. Younger broodmares, especially primiparous mares affected with udder edema, appear to be in more pain than older mares, and some of the mares so affected refuse to allow their foals to suckle.

Hypomagnesemia (chronic udder edema)

Disturbances in udder blood and lymph circulations

Excessively long dry period

Anemia

12.10.3 Agalactia

Any disease or condition that adversely affects the dam has the potential to compromise lactation. Agalactia, the failure of lactation after parturition, may be attributable to a primary endocrinologic or mammary gland problem, or it may be secondary to any of a multitude of systemic conditions and diseases (Boxes 12-23 and 12-24). True agalactia may be attributable to mammary gland anomalies or inadequacies among the numerous endocrinologic factors of development and pregnancy. Agalactia may be a complication of many conditions. In some animals the conditions to which agalactia is secondary manifest as alterations in a specific system, whereas other animals with agalactia may demonstrate such signs as fever, weight loss, anorexia, and anemia. Inadequate nutrition is rarely the cause of clinically observed agalactia. Fescue grass toxicity, caused by ingestion of the ergot alkaloid-

producing *Acremonium coenophialum*, is an important cause of agalactia and hypogalactia[189,190] (see Fescue Toxicity).

Agalactia should not be confused with failure of milk ejection (milk letdown). Administration of oxytocin may enhance milk letdown but does not affect milk production. Oxytocin stimulates a release phenomenon that acts on previously secreted and stored milk. Although somatotropin may increase milk production in a normally lactating cow, its effect on agalactia has not been adequately studied.

Inexperienced or nervous mares with adequate milk are often reluctant to allow their offspring to nurse, in part because of the mare's inexperience. Such nervous mares need not necessarily be primiparous mares. Although not allowing their offspring to nurse is usually a manageable behavior problem, the mare's udder should be examined for evidence of periparturient edema, inflammation, and painful conditions. 215 216

12.10.3.3 APPROACH TO DIAGNOSIS OF AGALACTIA

An accurate reproductive history should be obtained. It should be determined whether the dam is primiparous or multiparous. If primiparous, is she manifesting anxiety in the presence of her offspring? If multiparous, has she been agalactic at previous parturitions? Has she sustained recent trauma, perhaps during parturition, or was there exposure during gestation to infectious diseases or toxic plants? After a history has been determined

and the dam and neonate have been observed, attempts to facilitate the youngster's suckling might be indicated. Is the dam agalactic, or does she simply refuse to let the neonate suckle? Such measures as twitching or tranquilizing the nervous and inexperienced mare may resolve that problem. If assessing the dam's behavior toward her offspring does not resolve the problem, a thorough physical examination should be initiated. The objective now should be to rule out or incriminate infectious and inflammatory conditions contributing to the agalactic state. The dam herself may be systemically affected, or the problem may be localized in the udder or a mammary gland.

In listing causes of agalactia and hypogalactia in Boxes 12-23 and 12-24, we included only those that have a direct effect on the anatomic integrity of the mammary gland or its function. Abnormalities involving any system may compromise lactation.

12.10.4

Galactorrhea and Precocious Mammary Gland Development

Galactorrhea, the abnormal manifestation of lactation (not the secretion of true milk), occurs occasionally from the primordial mammary gland of young foals and ruminants, including neonates.[179] The serous secretion occurs in association with swelling of mammarian tissue in males and females and may be caused by transplacental transmission of maternal steroid hormones[191] (Box 12-25). The secretion is popularly known as *witch's milk*.

12.10.4.1

Box 12-25 Causes of Galactorrhea and Precocious Mammary Gland Development in Horses and Ruminants

Impending abortion

In utero death of one twin fetus

Spontaneous (inappropriate prolactin secretion)

Placental separation

Zearalenone toxicity

Pregnancy (especially multiple fetuses)

Suckling

Pseudopregnancy (caprine)

Ascending infection during pregnancy, placentitis

Ovarian tumors

Precocious mammary gland development and galactorrhea occur in pregnant and nonpregnant mares and in some of the ruminant species. Such premature udder development and subsequent lactation have been observed in nonpregnant and nonsuckled doelings and heifers.[179,192] Udder development and subsequent lactation have been observed in young nonpregnant heifers and does being suckled by other young animals.[179] In addition to the continued stimulation of suckling, other causes of premature mammarian development and lactation may be trauma and diseases of the pituitary, ovarian, and adrenal glands.[179] Zearalenone toxicity has been implicated in precocious mammary gland development and lactation in heifers.[193] Milk production is nonphysiologic in that it is of insufficient quality and quantity and does not justify milking the affected animals. There is no evidence that such abnormal development compromises normal lactation after parturition.[179]

Inappropriate lactation has been observed at various stages of pregnancy in most domestic species.[179] The most common cause of galactorrhea is abortion. Lactation may commence before or even without expulsion of the dead fetus. Lactation during pregnancy has also been observed in association with multiple fetuses, placentitis, and ovarian tumors. Accordingly, premature mammary gland development during gestation should be considered a warning of impending abortion, and the dam should be examined. Occasionally, pregnant mares develop mammarian enlargement during middle to late gestation that spontaneously regresses.[190] Some of these mares begin to lactate before parturition. It must be kept in mind that premature lactation, and subsequent loss of colostrum, is one of the most important causes of failure of passive transfer of immunoglobulins.[194]

Gynecomastia, the abnormal development of the male's mammary glands, has been observed in bucks in which rudimentary mammary glands and associated teats underwent development.[179,192] The aberrant structures, located on both sides of the buck's scrotum, can secrete up to 1 L daily of a substance that resembles milk. The cause is presumed to be endocrine imbalance but has not been determined. Lofstedt and colleagues[195] reported adrenal neoplasia as a cause of lactation in a wether.

11 Chapter 11 Alterations in the Skin

Stephen D. White

Anne G. Evans

11.1 GENERAL APPROACH TO DISEASES THAT ALTER THE SKIN

It is important to remember that the skin has a limited repertoire with regard to its presentation; many diseases with various causes may manifest with similar lesions. However, certain patterns of response to disease are also recognized. In order to manage skin problems successfully, the veterinarian must use a systematic approach by obtaining a complete history, performing a thorough physical examination, and, when appropriate, using one or more simple diagnostic techniques.[1] The following sections discuss the materials and methods necessary to perform techniques commonly used to diagnose large animal skin disease.

11.1.1 History

To obtain a differential diagnosis list, all the questions listed on the sample history form (Fig. 11-1) should be answered. Often it is helpful to repeat the questions to the owners at a later time or to give them a history form to complete at their leisure, which allows greater opportunity to remember details relevant to the skin disease. The goals should be to determine the initial features of the skin disease, how the problem has progressed, and what factors have influenced its progression to the present state.

11.1.2 Physical Examination

The diagrams and terms listed on the sample form (Fig. 11-2) may serve as a useful guide for recording the physical findings. The animal's overall condition should be assessed and a general physical examination should be performed to determine if the disease is limited to the skin or if systemic signs of disease are also present. The distribution, morphology (e.g., papules, nodules, wheals, patches of alopecia), and size of skin lesions should be noted. The mucous membranes also should be examined, and the skin surface palpated to determine features not readily noted visually (e.g., crusts beneath the hair, dryness, ability to epilate hairs, and presence of peripheral lymphadenopathy).

The practitioner's goal should be to describe accurately the animal's clinical appearance in a written record for future reference.

11.1.3 Diagnostic Techniques

For most of the techniques that follow, a good-quality microscope equipped with ×4, ×10, ×40, and ×100 objectives is recommended.

11.1.3.1 SKIN SCRAPINGS

Skin scrapings are used primarily to demonstrate microscopic ectoparasites, specifically mites. Scraping is a quick, simple, inexpensive diagnostic technique that is more useful in ruminants than in horses because equine

mite infestations are relatively uncommon. The materials needed to perform a skin scraping are a sterile container, mineral oil, a medical grade spatula (Fisherbrand Microspatula with Flat-Ended Blade, catalogue no. 21-401-20, Fisher Scientific; www.fisherscientific.com), glass slides, and cover slips. Although a No. 10 scalpel blade may be used, a medical grade spatula will not cut the skin in cases of sudden movement of the horse, yet is just fine enough to be able to scrape deep enough to find *Demodex* species mites, if indicated. If the hair coat is thick, a small area should be clipped before scraping. Multiple superficial scrapings that cover large surface areas should be performed, as well as several scrapings covering a small area that are deep enough to create capillary oozing. The collected material should be placed in a container until it can be examined microscopically. Some of the sample can then be placed on a glass slide and finely dispersed in enough mineral oil to provide a confluent layer without air bubbles beneath a cover slip. The slide should be scanned systematically with the ×10 objective. If something of significance is noted, the ×40 objective can be used to examine the specimen in more detail.

11.1.3.2

DERMATOPHYTE CULTURE

The materials necessary to perform a dermatophyte culture include dermatophyte test medium, mosquito forceps, a medical grade spatula, and sterile empty containers such as evacuated blood collection tubes. The forceps should be sterile, and each lesion to be sampled should be wiped gently with either water or isopropyl alcohol (there is some controversy as to which is better; I use water out of concern that the alcohol may inhibit fungal growth on the culture medium) to remove as many bacterial and fungal contaminants as possible and allowed to dry. Multiple small, scaling, and slightly crusted lesions should be sampled; the samples should be stored in individual containers. Broken hairs, scales, and crusts from the periphery of the lesions are collected (because dermatophytes cause peripherally expanding lesions). A spatula may be useful for scraping scales and debris from the skin surface. The forceps are used to pluck broken hairs.

Fig. 11-1 Sample dermatologic history form.

DERMATOLOGY HISTORY FORM

Owner_____ Date_____

Animal's name_____ Case #_____

Age of animal_____

Age when purchased_____ Age when skin problem started_____

Where on the body did the problem start?_____

What did the skin problem look like initially?_____

How has it spread or changed?_____

What season did the problem start?_____

Is the problem seasonal or year round?_____

If seasonal, what seasons is the disease present?_____

Does the animal itch?_____ If so, where?_____

Do any animals contacting the affected animal have skin problems?_____

Do any people in contact with the animal have skin problems?_____

Is fly control used?_____ If so, describe_____

Do any relatives of this animal have skin problems?_____ If yes, explain_____

List injectable, oral, or topical medications that have been used before and after onset of the disorder_____

Which medications were of benefit?_____

Which medications aggravated the condition?_____

Describe the environment where the animal is kept, including bedding_____

What is the animal fed?_____

Any additional information you feel is relevant to the skin disease_____

Fig. 11-2 Sample dermatologic physical examination form.

DERMATOLOGY PHYSICAL EXAMINATION FORM

Date_____

Distribution of lesions:

_____

_____

_____

Primary lesions (circle):

Macule	Patch	Papule
Pustule	Vesicle	Bulla
Wheal	Nodule	Tumor

Secondary lesions (circle):

Scale	Erosion	Excoriation
Fissure	Ulcer	Lichenification
Erythema	Alopecia	Hyperpigmentation
Crust	Comedone	

Pruritus_____ Epilation_____

Skin thickness_____ Skin tone_____

Hair coat_____ External parasites_____

Diagnostic workup:

Skin scrapings_____

KOH preparation_____

Dermatophyte culture_____

Acetate tape prep_____

Dermatophilus prep _____

Histopathology_____

Immunofluorescence_____

Microfilarial prep_____

Bacterial culture & sensitivity_____

Differential diagnosis:_____

Initial therapy:_____

If the clinician's practice performs its own fungal cultures, the samples should be removed from the containers with a sterile forceps in a clean working area and gently pressed onto, but not buried beneath, the culture medium. The top of the culture dish or vial should be loosely replaced to allow sufficient ventilation for the culture to grow. Most dermatophytes grow at room temperature, except for some strains of *Trichophyton verrucosum*, which requires incubation at 37° C (98.6° F). The colony usually first appears in 5 to 7 days, although all cultures should be allowed to incubate for 3 weeks before a negative result is declared.

Dermatophyte test medium is an amber-colored Sabouraud's dextrose agar containing phenol red, a pH indicator, and several antibacterial and antifungal agents to inhibit growth of contaminant organisms. Dermatophytes preferentially use the protein in the medium as they begin to grow, producing alkaline metabolites that cause the medium to turn red. The dermatophyte colony is typically a white to beige, powdery to fluffy growth; the colonies are never dark colored. Most saprophytic (contaminant) fungi metabolize the carbohydrates first, producing acidic metabolites that do not change the color of the medium. It should be stressed that after the carbohydrate source has been depleted, saprophytes use the proteins and produce a red color change.

Positive identification of a dermatophyte is made in most instances if a white to beige, powdery to fluffy colony begins to appear on the medium at the same time or within 24 hours of the appearance of a red color change in the medium (Fig. 11-3). An infrequently encountered exception to this rule is growth of the saprophyte *Scopulariopsis brevicaulis*, a tan to light brown, smooth or mealy colony that produces a concurrent red color change in the medium. It is essential to check the cultures daily to determine if the red color change and colony growth occur nearly simultaneously. If any doubt exists about the type of colony growth, the sample should be submitted to a diagnostic laboratory for specific identification.

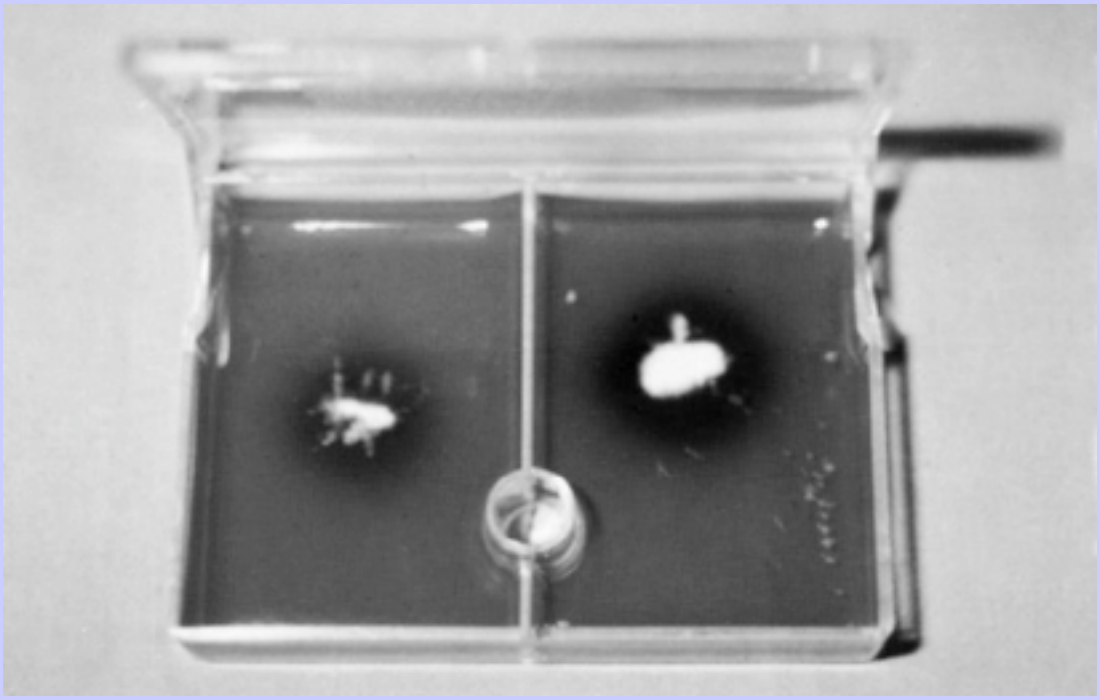
11.1.3.3

POTASSIUM HYDROXIDE PREPARATION

A potassium hydroxide (KOH) preparation may permit immediate diagnosis of dermatophytosis. However, examination of KOH preparations requires considerable experience, as fungal elements may be easily overlooked (false-negative result) and numerous artifacts such as fibers, cholesterol crystals, or oil droplets may be mistaken for fungal elements (false-positive result). It is always advisable to perform a dermatophyte culture in conjunction with a KOH preparation.

The materials necessary to perform a KOH preparation include mosquito forceps, a medical grade spatula, a sterile empty container, glass microscope slides, cover slips, a Bunsen burner, and clearing solution. As with a dermatophyte culture, it is important to sample several lesions to increase the chances of obtaining a diagnostic sample. Hairs and scales are collected from the periphery of the lesions with the mosquito forceps and the spatula. The samples are stored in the sterile container until a microscopic examination can be performed. A drop of the KOH clearing solution is placed on a glass slide, hairs and scales are added to the solution, and a cover slip is placed over the material. The slide should be scanned systematically with the ×10 objective for abnormal-appearing hairs with a fuzzy internal structure. If these features are noted, a higher-powered objective should be used for more detailed examination. A positive result with a KOH preparation demonstrates hyphae, which usually are uniform in width and septate. Beadlike chains of arthroconidia may be seen as well (Fig. 11-4).

Fig. 11-3 Positive result on dermatophyte culture. Growth of light-colored colony and simultaneous red color change are shown on dermatophyte test medium (right half of culture plate). Growth of dermatophyte on rapid-sporulating medium is shown on left half of culture plate.



The purpose of the clearing solution is to dissolve the hard keratin and bleach the melanin of the hair shaft so that the fungal hyphae and arthroconidia can be identified more readily. Care should be taken not to spill any clearing solution on the microscope because it can damage the lenses. Several types of clearing solutions are available. If 15% KOH is used, the slide should be heated for 15 to 20 seconds to facilitate clearing before examination. As an alternative, the preparation can be allowed to stand at room temperature for 30 minutes before viewing.

11.1.3.4

ACETATE TAPE PREPARATION

Acetate tape preparations for parasites are used primarily to diagnose infection with *Oxyuris equi*, although they may also be used to diagnose *Chorioptes* species. The materials required to perform an acetate tape preparation include acetate (nonfrosted) tape, mineral oil, and glass microscope slides. A piece of the tape is pressed over several areas in the anal and perianal region when looking for *O. equi* or over an affected region that has been lightly clipped when looking for *Chorioptes* species. The tape is then placed with the adhesive side down on a line of mineral oil that was placed lengthwise on a glass microscope slide. The purpose of the oil is to help clear the debris and facilitate examination of the preparation for parasites. The preparation is scanned with the ×10 objective for organisms.

11.1.3.5

DERMATOPHILUS PREPARATION

This test is used as an aid in identification of *Dermatophilus congolensis*. Crusts should be removed from the patient and the excess hair carefully trimmed from the crusts with a small pair of scissors. The crusts are minced with the scissors and mixed with several drops of saline on a glass slide. After the crusts have softened in the saline for several minutes, they should be crushed with the tip of an applicator stick. The excess debris is removed, and the slide is allowed to air dry. The slide should then be heat fixed; stained with Gram, Giemsa, or Wright stain; and examined for the characteristic bacteria. *D. congolensis* organisms are gram-positive, branching, filamentous bacteria that divide horizontally and longitudinally, forming parallel rows of cocci (zoospores) that commonly are described as resembling "railroad tracks" (Fig. 11-5).

11.1.3.6

CYTOLOGIC STUDIES

Cytologic studies are of value when dealing with crusts, scales, pustules, vesicles, nodules, or tumors. They can quickly indicate the presence of infectious organisms and provide a rough assessment of the spectrum of cell types present in a lesion (e.g., neoplastic, acantholytic, or inflammatory). The surface of the lesion should be gently shaved (if necessary); particular care must be taken not to rupture fragile pustules and vesicles or remove crusts. Crusts and scales are best evaluated by performing a superficial scrape with a spatula, placing the material on a microscope slide, heat-fixing, then staining with Gram, Giemsa, or Wright stain. Alternatively, acetate tape may be used to collect the material, and instead of placing the tape on a slide that has mineral oil (as is done when looking for parasites), the tape is placed on a slide on which several drops of the "blue" solution from the Wright stain have been placed. Scan for areas of interest with the ×4 objective, then use the ×100 objective with immersion oil.

181

182

Fig. 11-4 Positive result on potassium hydroxide (KOH) preparation. Note the small, spheric fungal elements (arthroconidia) on the hair shaft.

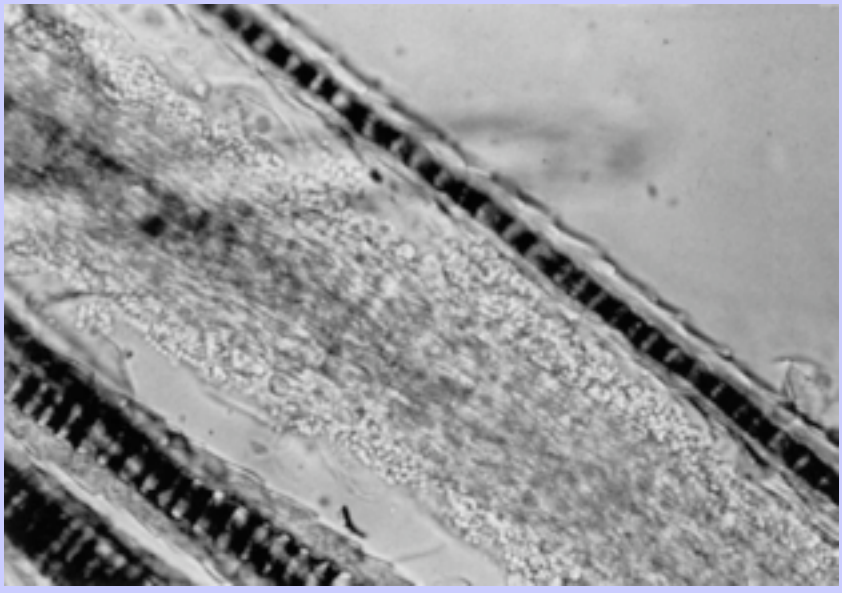


Fig. 11-5 Positive result on *Dermatophilus* preparation. *Dermatophilus congolensis* is a large, gram-positive, filamentous bacterium that divides horizontally and longitudinally, forming parallel rows of cocci (zoospores) that are commonly described as "railroad tracks."

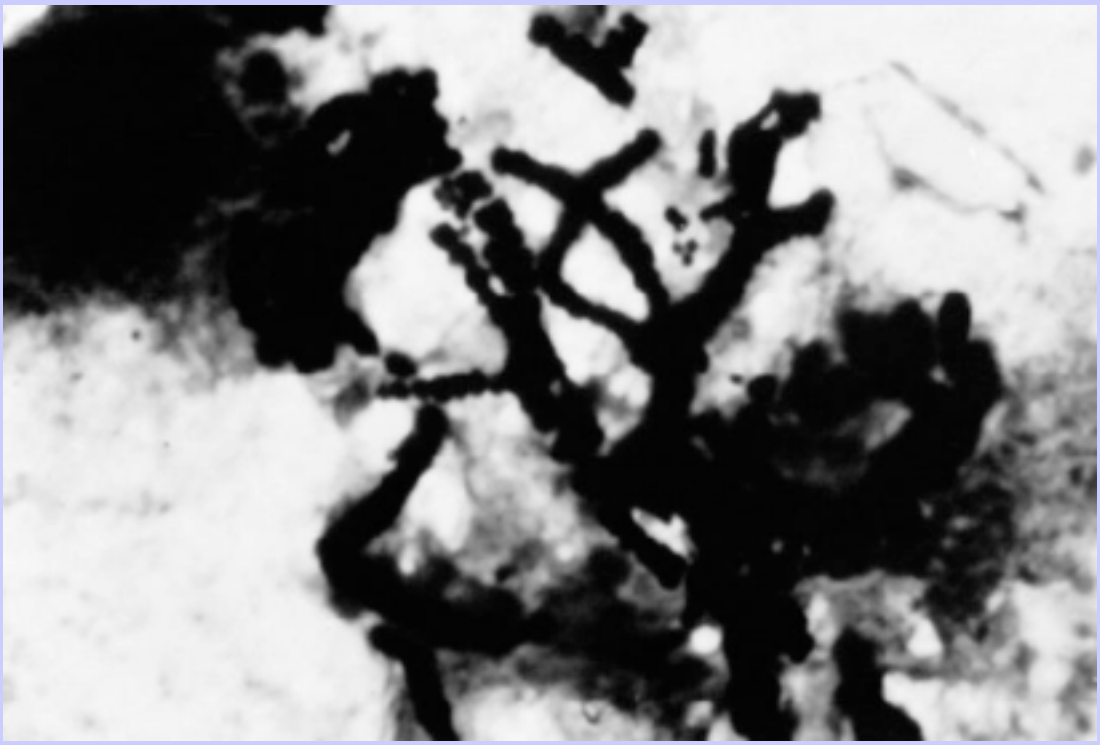


Cytologic evaluation of intact pustules and vesicles is best accomplished by gently opening an intact lesion with the tip of a sterile No. 15 scalpel blade or 25-gauge needle and smearing the contents on the surface of a glass slide. The slide should be air dried, heat fixed, stained with one of the previously mentioned stains, and examined. Nodules, tumors, and swellings are best evaluated by fine-needle aspiration. A 25- or 22-gauge needle on a 12-mL syringe is introduced into the mass, and negative pressure is applied. Several passes through the mass at different angles should be performed. After negative pressure has been released, the needle is removed from the mass. The needle is then removed from the syringe, the syringe is filled with air, and the needle is reattached. The contents of the needle are pushed out onto glass slides, which are subsequently dried, fixed, and stained as described previously.

11.1.3.7

BIOPSY FOR ROUTINE HISTOPATHOLOGIC EXAMINATION

The following materials are needed to perform a skin biopsy:

- 6-mm and 4-mm biopsy punches

- No. 15 scalpel blade
- Sharp scissors
- Curved mosquito forceps
- Needle holders
- No. 2-0 or 3-0 nonabsorbable suture
- 2% lidocaine
- 3-mL syringe with a 22- to 25-gauge needle
- Tongue depressor or cardboard
- Gauze
- 10% buffered formalin

It is very important *not* to surgically prepare a lesion that is going to be biopsied for histopathologic examination. Shaving and scrubbing remove crusts and epithelial tissue that may be important in reaching a diagnosis. Cutaneous infections caused by biopsies taken in this manner are extremely uncommon. If the clinician is concerned about infections, surgically prepare the site *after* the biopsy has been taken, before suturing.

Local anesthesia is sufficient for obtaining most skin biopsies. A 22- to 25-gauge needle is inserted at the margin of the lesion until the bevel is buried in the subcutaneous tissue beneath the lesion. The 2% lidocaine (0.5 to 1 mL) is injected, allowing 1 to 2 minutes for the anesthetic to take effect. Infiltration of the dermal or epidermal tissue with lidocaine should be avoided because this causes artifactual changes in the specimen.

Four techniques can be used to biopsy skin: the excisional, wedge, punch, and elliptic techniques. When the lesion to be sampled is a single nodule, the ideal biopsy technique is excisional because the lesion can be eliminated at the same time the histologic diagnosis is made. If the lesion is a tumor and too large to be excised, a generous wedge biopsy should be performed, which ideally extends from the margin to the center and includes the full depth of the lesion.

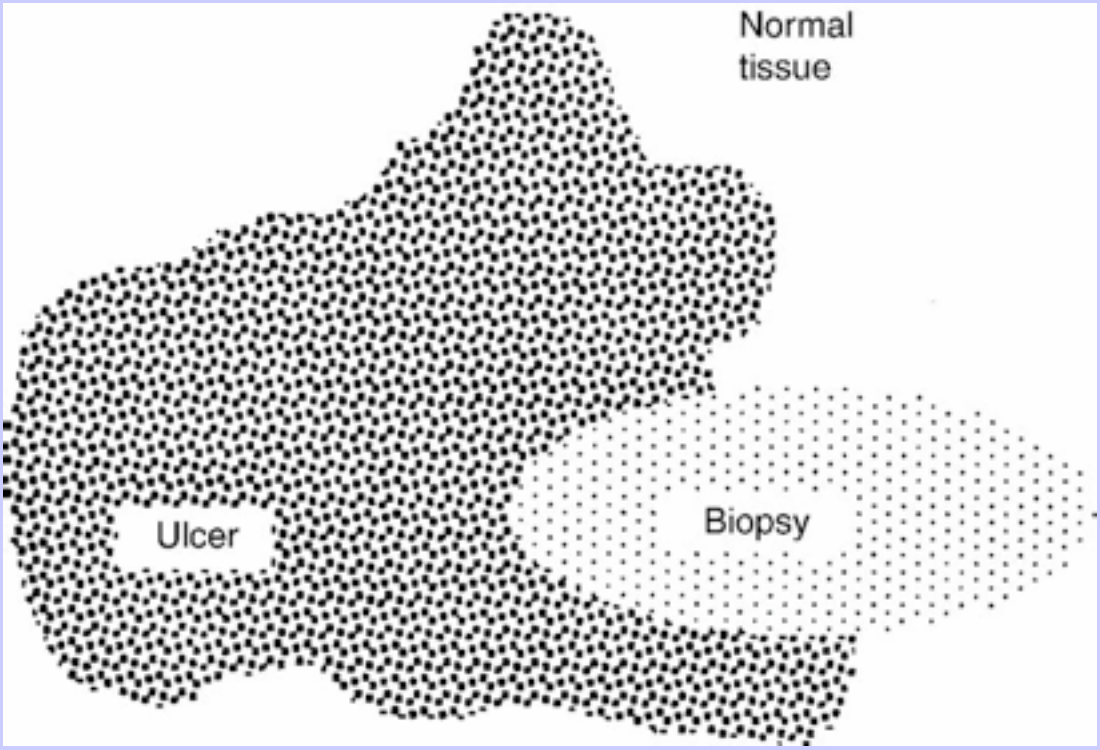
Most lesions can be sampled with a 6-mm biopsy punch. A disposable biopsy punch* usually can be used to obtain two or three biopsies before its edge is dulled and it must be discarded. The punch is placed directly over the lesion and rotated in a continuous circular motion while pressure is applied until the blade of the punch is in the subcutaneous tissue. If the punch has cut to a sufficient depth, when it is removed the tissue sample is free of the adjacent dermis and remains only loosely attached to the underlying subcutaneous tissue by a thread of connective tissue. A small pair of curved mosquito forceps is used to gently grasp the subcutaneous part of the biopsy and elevate it from the surrounding tissue. The specimen is then cut free with a pair of sharp scissors. It is important to avoid handling the epidermal and dermal parts of the sample during this procedure to minimize artifactual changes in the tissue sample. The sample is gently blotted to remove any surface hemorrhage and immediately placed in 10% buffered formalin for fixation. The site from which the sample was taken may then be cleaned with an antiseptic solution and closed with either two simple interrupted sutures or a cruciate stitch using No. 2-0 or 3-0 nonabsorbable sutures.

Although punch biopsies are convenient and easy to use, they are not appropriate for vesicular, bullous, and ulcerative lesions. For these lesions the method of choice is a surgical elliptical biopsy. The biopsy of vesicular and bullous lesions should encompass the entire lesion. Biopsy of samples of ulcerations should include abnormal tissue, the leading edge of the lesion, and normal tissue. Because an ulcer lacks epithelial tissue, the leading edge where epithelium remains may be the most rewarding in providing a histologic diagnosis. Thus the skin is biopsied so that the long axis of the ellipse crosses perpendicular to the leading edge of the ulcer (Fig. 11-6). It is important to mount surgical elliptical biopsies before placing them in formalin or they will curl during fixation, resulting in distortion of the histologic features during sectioning. To mount the specimen, the subcutaneous surface is placed on a small piece of a wooden tongue depressor or cardboard while gentle pressure is applied to the tissue so that it adheres to the surface; then the specimen is placed in the formalin.

182

183

Fig. 11-6 An ulcerative lesion should be biopsied in an elliptical fashion, using a No. 15 scalpel blade, so that the long axis of the ellipse crosses perpendicular to the leading edge of the lesion.



Ideally biopsy specimens should be submitted to a veterinary histopathologist with special interest and training in dermatopathology. Submission of adequately biopsied specimens of properly chosen lesions is the clinician's responsibility. To further increase the chances of securing clinically valuable information from the biopsy samples, the clinician must also provide the pathologist with a concise history of the skin problem, physical findings, a description of the morphology and location of the lesions, and a list of differential diagnoses. When the suspected clinical diagnoses are provided, the pathologist's efforts can be directed specifically toward confirming or ruling out those diagnoses.

* Baker's Biopsy Punch, Chester A. Baker Laboratories, Miami, FL.

11.1.3.8

BIOPSY FOR IMMUNOPATHOLOGY

Immunopathology may be used as an adjunct to conventional histologic testing when the clinician suspects that the patient has an immune-mediated skin disease. The two methods used are direct immunofluorescence, which requires a special medium for fixation (Michel's fixative), and immunoperoxidase techniques, which may be performed on the paraffin block prepared for the histopathologic study (i.e., the formalinized tissue section). The materials and the technique for biopsy for immunopathology are essentially identical to those for a routine histologic examination. Administration of corticosteroid medications within 3 weeks of testing may be associated with false-negative test results. It is advisable to bisect biopsy samples along their long axis, submitting half for direct immunopathology and half for histopathologic examination. It should be borne in mind that histopathology of the lesions, rather than immunopathology, is often the more accurate of the two methods in the diagnosis of autoimmune diseases; thus if faced with the choice (because of financial reasons or paucity of lesions) the clinician should always choose the former.

11.1.3.9

MICROFILARIAL PREPARATION

The microfilarial preparation technique is applicable to the diagnosis of cutaneous onchocerciasis in horses, stephanofilariasis in cattle, and elaeophorosis and parelaphostrongylosis of sheep and goats. After selecting the lesion to be sampled, a 6-mm punch biopsy is used to obtain the tissue sample in the same manner as for the histopathologic biopsy. The tissue should be split, and half preserved in 10% buffered formalin for routine histologic studies. The other half is placed on a dampened gauze sponge in a tightly closed container until the preparation can be performed. A small piece of the tissue that includes the dermis is placed on a glass slide and minced with a razor blade; a few drops of nonbacteriostatic saline are added. Bacteriostatic saline, which kills the microfilaria and thus makes their identification more difficult, should not be used. The specimen is incubated at room temperature for 15 minutes. The slide is then scanned with the ×4 objective along the margins of the tissue debris while the clinician searches for indication of motion in the saline. If the characteristic whiplash movement of the parasite is noted, a higher-powered objective should be used. If the preparation result is negative, a small amount of water is added to a Petri dish, the glass slide is rested on two wooden sticks above the water, and the cover is replaced on the dish. The preparation should be incubated for several hours or overnight and reexamined. The Petri dish helps prevent the sample from drying out.

11.1.3.10

BACTERIAL CULTURE

The method of bacterial culture depends on the type of lesion. All haired lesions should be gently shaved. Nodules and tumors should be cultured by aseptically excising the lesion or by obtaining a generous wedge of the tissue. To prevent culture contamination by surface bacteria, the nodules should be gently shaved, washed with an antiseptic soap, and dried with a sterile gauze pad. A perilesional injection of 2% lidocaine is used to anesthetize the tissue. The sample is placed in a transport medium and sent to a microbiology laboratory for culture. A papular eruption (rash) is best cultured by obtaining a sterile 6-mm punch biopsy of skin.

Crusts may be lifted up and the underside cultured via a sterile Culturette. Ulcerative lesions should not be cultured because any bacteria isolated are more likely to be opportunistic rather than primary pathogens. If the lesions are fluctuant (vesicles, pustules), the overlying skin can be opened gently with a No. 15 blade and some of the contents of the lesion transferred with the blade to the tip of a sterile culture swab. It is advisable

to avoid placing the swabs directly on the skin surface, particularly when sampling small lesions, because nonpathogenic bacteria from the skin surface may be inadvertently cultured.[1]

11.1.3.11 SUBCUTANEOUS AND DEEP FUNGAL CULTURE

Subcutaneous and deep fungal cultures should be performed on nodules, tumors, and swellings. The technique is identical to that described for bacterial culture of these lesions.

11.2 PRURITUS

11.2.1 Definition

Pruritus is an unpleasant sensation that provokes the desire to scratch. It is designated a primary cutaneous sensation, along with heat, cold, pain, and touch. There are two broad categories of pruritus. Physiologic or spontaneous itch is a sharp, well-defined, pruritic sensation that is sufficiently intense to prompt scratching but that does not result in significant irritation of the skin; this is a frequent daily occurrence in normal individuals. Pathologic itch is the less well-defined pruritus that occurs in a variety of primary and secondary skin disorders and in systemic diseases. It is an intense cutaneous discomfort that provokes vigorous scratching.[2]

11.2.2 Mechanisms of Pruritus

The investigation of the mechanism of pruritus has been primarily in laboratory animals and humans. It is presumed that much of this knowledge is applicable to other animal species. Pruritus is a distinct sensory quality transmitted from an arborizing network of nerve endings situated at or near the dermoepidermal junction. The sensation is carried to the spinal cord through small, unmyelinated C fibers. The fibers enter the dorsal root of the spinal cord and ascend in the ventrolateral spinothalamic tract through the posterior ventral nucleus of the thalamus to the sensory cortex. The pruritic sensation may be modified in the sensory cortex by behavioral factors or competing stimuli.[3,4]

183
184

Many physical and chemical stimuli can evoke pruritus, and many substances have been implicated as mediating pruritus in humans. Examples of these mediators, which are assumed to have importance in domestic animals as well, include the following[4]:

- *Histamine*. Histamine has been regarded as the classic mediator of pruritus. Histamine is present in mast cells in the dermis and in blood basophils. An intradermal injection of histamine produces pruritus within 20 to 50 seconds. Because many pruritic disorders respond poorly to antihistamines given either therapeutically or prophylactically, histamine is not believed to be the sole mediator of pruritus.
- *Endopeptidases*. Examples include trypsin, papain, and kallikrein.
- *Prostaglandins*(*E series* and *endoperoxidases*). Prostaglandins induce pruritus by potentiating the release of proteases from keratinocytes and leukocytes and by lowering the threshold and increasing the duration of histamine-induced pruritus.
- *Endogenous opioid peptides*. Opiates may potentiate preexisting pruritus. The opiate antagonist naloxone hydrochloride has an attenuating effect on the histamine-induced component of pruritus.

- *Substance P*. Substance P is a neurotransmitter found in the central and peripheral nervous systems. When introduced intradermally, it elicits a pruritic response.

Many factors can potentiate existing pruritus. Neurologic factors such as boredom and fatigue can potentiate a pathologic itch and possibly transform a physiologic itch into a pathologic itch. Local axonal reflexes can potentiate pruritus; that is, if a second stimulus is applied to an area close to one that is pruritic, the second stimulus, irrespective of its type, is perceived as an itch. In addition, skin with chronic dermatitis has limited perception of stimuli, and any stimulus applied to the affected region may be perceived as either a burning sensation or an itch. This phenomenon is known as "conversion itch." Secondary bacterial infections, vasodilatation, and inflammation result in a local increase in proteases that potentiate pruritus.[3]

Pruritus can be diminished by several nonpharmacologic mechanisms, the most common being application of competing stimuli. Pruritus is a minor sensation compared with the other primary sensations of heat, cold, touch, and pain; thus local application of a competing stimulus to a pruritic area often suppresses the pruritic sensation. Scratching is an example of a competing stimulus. Scratching may relieve pruritus by disturbing the rhythm of afferent impulses traveling toward the central nervous system. An alternative theory is that scratching may cause transient damage to nerve fibers that convey the pruritic sensation. Unfortunately the effect is short-lived because the epidermal damage induced by scratching causes the release of epidermal proteases that may later increase the degree of pruritus. Centrally acting factors such as diversions or distractions can also diminish the perception of pruritus by providing competing stimuli directly to the cortex rather than locally to the skin.[3]

11.2.3

Approach to the Diagnosis of Pruritus

Pruritus is the most common sign of cutaneous disease. Most often in large animals it is caused by ectoparasites or a hypersensitivity reaction, or both (e.g., *Culicoides* hypersensitivity), but it may also be caused by cutaneous bacterial or fungal infections (e.g., dermatophytes, *Malassezia* species) (Box 11-1). Because pruritus may be a feature of a more generalized disease process, it is important to take the patient's general health into account. Hypersensitivity reactions, which are commonly pruritic, may or may not be limited to the skin. For example, anaphylaxis is a life-threatening hypersensitivity reaction that may manifest as pruritus in its early stages. Other pruritic skin diseases include immune-mediated diseases such as pemphigus foliaceus; direct irritation by chemicals; and photoactivated dermatoses. It is helpful to formulate a differential diagnosis by considering each of these broad categories of diseases and using historic information, other cutaneous signs, and appropriate diagnostic tests to narrow the list of differential diagnoses.

Staphylococcal pyoderma (horses)

Dermatophytes

The following steps are a guide to the diagnosis of pruritus in the horse and ruminant:

1 History and physical examination (see Fig. 11-1).

a Determine if the pruritus is a seasonal or year-round problem. A seasonally recurrent pruritic disease tends to suggest either seasonal exposure to a parasite (e.g., lice in the winter, flies in the summer) or a seasonal environmental allergen (e.g., pollens) as the cause. Determine the level of fly exposure for the animal that is pruritic in the warmer months.

b Determine if the pruritus is generalized or localized, and if localized, what areas of the body are affected. For example, photoactivated dermatoses are limited to the white-haired regions.

c Determine if contact animals of the same and different species are affected or unaffected. The presence of multiple pruritic animals is suggestive of a contagious disease (e.g., dermatophytes, ectoparasites) or a disease of common exposure *(Culicoides)*. A single pruritic animal among a group of unaffected animals is more likely to be experiencing a hypersensitivity reaction (drug or environmental).

d Determine what topical and systemic medications were given to the patient both before and after the onset of the problem. Medications given before onset may be the cause of the pruritus, and those given after onset may interfere with the results of diagnostic tests.

e Determine whether all the cutaneous lesions can be attributed to self-trauma or if other primary cutaneous changes are present (e.g., wheals, nodules, pigmentary changes).

f Determine whether, on close inspection, the coat shows evidence of small but grossly visible parasites such as lice or their eggs.

2 The most useful diagnostic tests are skin scrapings, acetate tape preparations, dermatophyte culture plus KOH preparation, *Dermatophilus* preparation, microfilarial preparation, biopsy for routine histopathologic examination, and intradermal skin testing (see Chapter 40).

11.3 NODULES, TUMORS, AND SWELLINGS

11.3.1 Definition

A nodule is a circumscribed, solid elevation larger than 1 cm in diameter that does not deform when palpated. Nodules extend into the deeper layers of the skin and are usually the result of cellular infiltrates in the dermis or subcutis. *"Tumor"* is a less precise term that usually refers to a neoplastic, nodular enlargement of the skin or subcutaneous tissue.[3] The term *"tumor"* is most commonly used to describe very large nodular neoplasms. In addition to nodules and tumors, swellings include elevated lesions that pit with pressure (wheals) and fluctuant lesions (cysts and abscesses).

11.3.2 Mechanisms of Nodule, Tumor, and Swelling Formation

Nodular lesions can be subdivided into inflammatory and neoplastic lesions. Inflammatory nodules are composed of a massive mixed cellular infiltrate involving the dermis, the subcutis, or both. The inflammatory infiltrate may contain variable numbers of neutrophils, histiocytes, lymphocytes, plasma cells, and eosinophils. Cellular infiltration usually is stimulated by the presence of foreign material, and the nature of that material influences the composition of the inflammatory infiltrate. The foreign material may be infectious (parasite, bacteria, or fungi) or noninfectious (fibrin, crystalline material, or other inert substances). Grossly visible nodules develop as the masses of inflammatory cells accumulate in the tissues to phagocytize or wall off the foreign material. As the lesion enlarges, the dermis and subcutis are obliterated by the inflammatory infiltrate and the overlying epidermis may become atrophic, resulting in ulceration of the nodule's surface.

Most cutaneous and subcutaneous neoplasms form nodular lesions. Cutaneous and subcutaneous neoplasms may either arise from a cell type of the epidermis, dermis, or subcutis or less commonly metastasize from another tissue of origin. Cytologically and histologically neoplasms are composed of a uniform population of pleomorphic cells with variable atypia. Neoplasms may stimulate a secondary inflammatory reaction.

Swellings include solid lesions, such as nodules and tumors, as well as urticaria, cysts, and abscesses. Urticarial lesions (wheals, hives) are often transient, localized, inflammatory lesions caused by a vascular reaction in the dermis in which vasodilatation results in fluid transudation with or without erythema. The fluid is not compartmentalized but dispersed evenly throughout the dermal tissue. The result is an elevated lesion that, unlike a nodule, pits with pressure and often dissipates within minutes to hours as the fluid is resorbed. Typically a sparse, perivascular infiltrate that is usually lymphocytic is seen, although the infiltrate may be dense and intermingled with eosinophils. Urticaria is usually well circumscribed, although with confluence the edema may assume geometric shapes.

A cyst (Latin for *sac*) is an epithelium-lined cavity containing fluid or semisolid material.[3] A cyst usually presents as an elevated, smooth, well-circumscribed, fluctuant mass. Cutaneous cysts usually are lined by

adnexal epithelium (hair follicle, sebaceous or apocrine epithelium) and are filled with cornified cellular debris and sebaceous or apocrine secretions.

An abscess is a localized, fluid-filled, fluctuant lesion; if large enough, it may be ballotted. It results from a dermal or subcutaneous accumulation of the debris of dead cells and tissue elements liquefied by the proteolytic and histolytic enzymes elaborated by polymorphonuclear cells (e.g., pus). Abscesses most commonly result from localized infection, although they occasionally result from septicemia or may be sterile.

11.3.3

Approach to the Diagnosis of Nodules, Tumors, and Swellings

Nodules, tumors, and swellings may arise from a variety of cutaneous disorders and, in rare cases, as signs of a systemic disease. The major categories of diseases that should be considered when forming a differential diagnosis include hypersensitivity reactions, infectious diseases, sterile inflammatory diseases, and neoplasia (Box 11-2). The primary systemic diseases that should be considered are amyloidosis, lymphosarcoma, and anaphylaxis.

The following steps are a guide to the diagnosis of nodules, tumors, and swellings in horses and ruminants:

1 History (see Fig. 11-1). Pay particular attention to:

a Signalment. Older animals are at greater risk for cutaneous neoplasia (e.g., gray horses and melanomas). However, neoplasia is not restricted to older animals; equine sarcoids are frequently recognized in horses as young as 3 years of age.

b Number and progression of lesions. If one or only a few lesions are present, hypersensitivity to arthropod bites should be considered, particularly if there is rapid onset of the lesion. Rapid onset of generalized lesions such as urticaria suggests a differential diagnosis of drug, flying insect, environmental (pollen), or (rarely) food allergies.

c A recent history of systemic illness, which might suggest that the lesion is a bacterial abscess.

2 Physical examination (see Fig. 11-2). In particular:

a Determine by palpation if the cutaneous lesions are nodules, tumors, or swellings.

b Inspect the lesion or lesions closely for evidence of cutaneous parasitism (ticks, breathing pores associated with *Hypoderma* larvae, yellow granules associated with cutaneous habronemiasis).

c Determine if the lesions are painful or pruritic (e.g., evidence of excoriations).

3 Perform fine-needle aspiration for cytologic studies.

4 Perform biopsy for histopathologic examination.

5 Perform bacterial culture and sensitivity.

6 Perform subcutaneous and deep fungal cultures.

7 Perform dermatophyte culture and KOH preparation.

11.4 ULCERATIONS AND EROSIONS

11.4.1 Definition

An ulcer is a cutaneous defect that results from a complete loss of the epidermis and usually part of the underlying dermis.[3] Ulcers often heal with scarring that is caused by destruction of dermal collagen. An erosion is a cutaneous defect that results from a partial loss of the epidermis that does not penetrate beneath the basal laminar zone. Because an erosion does not involve the dermis, it heals without leaving a scar. Because the epidermis is a cutaneous barrier to invading microorganisms, ulcers and erosions often are secondarily infected.

11.4.2 Mechanisms of Ulcer and Erosion Formation

Ulcers and erosions are secondary lesions. Primary lesions develop spontaneously and are a direct reflection of underlying disease. Secondary lesions evolve from primary lesions or are artifacts induced by excoriation or external trauma. Primary lesions that may lead to the formation of ulcers and erosions include fluid-filled lesions such as pustules and vesicles. Rupture of these fragile lesions results in epidermal destruction and erosion or ulcer formation. Swellings such as abscesses and cysts may also rupture, resulting in ulceration, but these primary lesions are more stable and often remain intact. Nodules and tumors may become secondarily eroded or ulcerated. As the nodule or tumor enlarges, the mass exerts pressure on the overlying epidermis, leading to epidermal atrophy and ultimately a break in epidermal confluence, resulting in ulceration and erosion. The most common cause of ulceration and erosion is pruritus, which induces excoriation and hence epidermal destruction. Ulcers and erosions may also result from external trauma, such as epidermal destruction arising from mechanical, thermal, or chemical causes (Box 11-3).

11.4.3 Approach to the Diagnosis of Ulcerations and Erosions

To diagnose the cause of an ulcer or erosion, the clinician must first determine the primary lesion that resulted in ulceration and erosion. Ulcers and erosions occurring secondary to pustules and vesicles, to swellings such as

abscesses and cysts, to nodules and tumors, to pruritus, and to external trauma must be differentiated. The list of differential diagnoses relevant to each of these groups of primary lesions is then considered.

Viral diseases (in ruminants, for example, infectious bovine rhinotracheitis, vesicular stomatitis, bovine herpes mammillitis)

11.4.3.1.3

NEOPLASIA

Squamous cell carcinoma

The following steps are a guide to the diagnosis of ulcerations and erosions in horses and ruminants:

1 History (see Fig. 11-2)

a Determine if the animal is pruritic.

b Determine if the animal has been subjected to external trauma (mechanical, thermal, or chemical).

c Determine what topical and systemic medications were given to or used on the patient before the onset of the problem. Use of certain topical agents may suggest a diagnosis of contact dermatitis, whereas administration of systemic medications may suggest a drug hypersensitivity.

2 Physical examination (see Fig. 11-2)

a Examine the oral cavity and mucocutaneous junctions for lesions. Oral or mucocutaneous lesions (or both) in the horse might suggest accidental ingestion of a vesicant, or the rare diagnosis of bullous pemphigoid. In a ruminant these lesions often are seen with viral infections.

b Look for evidence of excoriation, suggesting that the ulcerations and erosions have occurred secondary to pruritus.

c Look for evidence of primary lesions such as pustules, vesicles, nodules, tumors, or swellings, which may have preceded the ulcerations and erosions.

3 Biopsy for routine histopathologic examination

4 Biopsy for direct immunofluorescence testing

11.5 PAPULES, PUSTULES, AND VESICLES

11.5.1 Definition

A papule is a solid, circumscribed, elevated lesion up to 1 cm in diameter. Papules are essentially small nodules that do not extend beneath the dermis. A pustule is a fluctuant, circumscribed, elevated accumulation of pus (inflammatory cells and often necrotic debris) up to 1 cm in diameter (e.g., a small abscess). Pustules are frequently associated with infectious diseases, although sterile pustular diseases (such as pemphigus foliaceus) exist. A vesicle is a fluid-filled, acellular, circumscribed, elevated lesion up to 1 cm in diameter. A bulla is a vesicle that is larger than 1 cm in diameter. All these lesions can be either follicular or nonfollicular in orientation, depending on the underlying cause. Pustules and vesicles are rarely seen clinically because of their fragility and hence their susceptibility to rupture. Because papules are solid lesions, they are more stable and therefore more commonly encountered.

186

187

11.5.2 Mechanisms of Papule, Pustule, and Vesicle Formation

Papules usually form as a result of an infiltrate in the dermis, which can be either cellular or noncellular. Cellular infiltrates may include inflammatory or neoplastic cells, although neoplastic papular lesions are relatively uncommon in large animals. Inflammatory infiltrates may be mixed, containing variable numbers of neutrophils, histiocytes, lymphocytes, plasma cells, and eosinophils, or one cell type may predominate. The composition of the inflammatory cells is influenced by the underlying cause of the papule, and the possible causes are extensive. Noncellular papular infiltrates include substances such as edema fluid, amyloid, and proliferative collagen. Epidermal hypertrophy may contribute to or be the sole cause of papule formation.

Pustules form as the result of an intraepidermal, subcorneal, or, less commonly, subepidermal accumulation of inflammatory cells. Infiltration of inflammatory cells, particularly polymorphonuclear leukocytes, leads to the release of proteolytic enzymes that liquefy tissue elements and result in the formation of a fluctuant lesion. Eosinophils, acantholytic cells, and infectious organisms may also be noted in a pustule, depending on the underlying cause. The stimulus leading to pustule formation is most commonly infectious, although pustules can result from noninfectious causes such as hypersensitivity reactions and autoimmune disease.

Vesicles form either at the dermoepidermal junction (subepidermal) or in the epidermis (intraepidermal) as a result of destruction of the basement membrane zone or confluence of intercellular edema (spongiosis). Clinically the two types of vesicles are indistinguishable. Vesicles form as the result of some viral diseases, during severe inflammatory reactions (allergic contact dermatitis), or with cutaneous physical damage (mechanical, chemical, or thermal). In pemphigus foliaceus, autoantibodies presumably bind to transmembrane proteins between the epidermal cells, causing disruption of epidermal intercellular attachments. The result is intraepidermal cleft formation that leads to vesiculation. In bullous pemphigoid, complement-activating antibodies bind to antigens in the basement membrane zone, causing degranulation of mast cells, chemotaxis of neutrophils and eosinophils, and release of tissue-destructive enzymes that injure the basement membrane zone. The result is loss of dermoepidermal adherence and vesicle formation.[3] Vesicles are transient, fragile lesions and therefore are rarely recognized clinically. If they are not destroyed by surface trauma, rapid infiltration by inflammatory cells transforms a vesicle into a pustule.

11.5.3

Approach to Diagnosis of Papules, Pustules, and Vesicles

Although papules, pustules, and vesicles may look somewhat similar on a cursory physical examination, the clinician must differentiate among the three and determine which of the lesions are present. Examination with a hand lens may help. The differential diagnoses relevant to papules, pustules, and vesicles are not necessarily the same (Box 11-4). In all cases it is important to determine if disease is limited to the skin or if the animal's general health is compromised as well.

11.5.3.1.2 RUMINANTS

11.5.3.1.2.1 Ectoparasites—Usually Papules

Sarcoptes scabiei

Psoroptes cuniculi (goats)

Lice

11.5.3.1.2.2 Infectious

Viral diseases (e.g., vesicular stomatitis)—vesicles

Staphylococcal pyoderma (goats)—pustules or papules

Papular lesions have the most extensive differential diagnoses:

- Hypersensitivity reactions. Parasitic hypersensitivities are the most common (e.g., *Culicoides* hypersensitivity), although drug and (rarely) food hypersensitivities should also be considered. Many hypersensitivity reactions are pruritic.
- Parasites. Some species simply irritate the skin with their bites (e.g., horn fly [*Haematobia irritans*]) without inducing a hypersensitivity reaction.
- Infectious diseases (bacterial, fungal, and viral). Typically papules caused by infections have a follicular orientation.
- Certain neoplastic diseases (papillomas or sarcoids).
- Uncommon causes, including autoimmune diseases, such as pemphigus foliaceus, and diseases of uncertain cause, such as equine sarcoidosis.

Pustules are most commonly associated with bacterial infections, although fungi and, in rare cases, parasites (*Demodex* species) can cause pustule formation. Sterile pustular diseases are less frequently seen (drug eruptions, sterile eosinophilic folliculitis of cattle)[5] but should be included in the differential diagnoses. Vesicles are rapidly infiltrated by inflammatory cells and transformed into pustules. Diseases commonly associated with vesicles include viral diseases of ruminants, autoimmune diseases, contact dermatoses, and burns.

The following steps are a guide to the diagnosis of papules, pustules, and vesicles in horses and ruminants:

1 History (see Fig. 11-1)

a In particular, determine whether the lesions are pruritic, painful, or asymptomatic.

b Determine if contact animals of the same and different species are affected or unaffected. If contact animals are affected, a contagious problem should be considered: fungal (dermatophytosis), bacterial (dermatophilosis), viral (contagious ecthyma), or parasitic (*Culicoides* hypersensitivity).

c Trace the temporal course of development. Rapid onset of lesions may suggest a hypersensitivity reaction.

187

188

d Check for seasonality. A seasonal problem suggests a parasitic or hypersensitivity (pollens) cause. Lice are a problem in the winter, trombiculidiasis tends to occur in the fall, and most of the flying insects are present in the spring, summer, and early fall.

e Determine what topical and systemic medications were given to or used on the animal before the onset of the problem. Use of certain topical agents may suggest a diagnosis of contact dermatitis, whereas administration of systemic medications may suggest drug hypersensitivity.

f Determine if the animal has been subjected to external trauma (thermal or chemical).

2 Physical examination (see Fig. 11-2)

a Gently palpate the lesions to determine if they are solid (papules) or fluctuant (pustules or vesicles).

b Note if the lesions have a follicular orientation, suggesting an infectious cause.

c Check for lesions involving the oral cavity and mucocutaneous junctions.

d Look for evidence of excoriation, suggesting that pruritus is a feature of the disease.

e Inspect the coat closely for small but grossly visible parasites such as lice or their eggs.

f Inspect contact animals for evidence of disease.

11.6 SCALING AND CRUSTING

11.6.1 Definition

Scale is a visible accumulation of fragments of the horny layer of the skin (stratum corneum); it represents the final product of epidermal keratinization.[3] The process of forming the stratum corneum is termed *cornification*. Histologically scale is recognized as hyperkeratosis and can be subdivided into parakeratosis (cornification with nuclear retention) or orthokeratosis (cornification without nuclear retention). In some conditions parakeratosis and orthokeratosis may be present together. Grossly the scale varies in appearance. The color may be white, silver, yellow, brown, or gray. The consistency may be bran-flake—like, powdery, coarse, greasy, or dry. Scale can be either loose or adherent to the skin or hair shafts.

Crusts are composed of variable amounts of serum, cells (leukocytes, erythrocytes, keratinocytes), fibrin, infectious agents (bacteria and fungi), debris, and/or medications. They often cover erosions or ulcerations. Heaped-up crusts are referred to as *vegetations*. On the basis of their histologic composition, crusts may be subdivided into cellular, serocellular, serous, and hemorrhagic types.

11.6.2 Mechanisms of Scale and Crust Formation

Scale results from increased desquamation (exfoliation) of the stratum corneum. Exfoliation is the final stage of keratinization, the process by which the permanent population of cells of the basal layer of the epidermis divides, undergoes specific patterns of differentiation, and progresses toward the surface, where it is shed.[3,5] Excessive exfoliation and scale formation occur when the rate of keratinization is accelerated; when trauma to the surface of the epidermis (chemical, mechanical, or thermal) loosens the stratum corneum; or when the structures sustaining epidermal intercellular cohesion (such as transmembrane proteins) are destroyed, resulting in a loss of cohesion between epidermal cells.

Because crusts are composed primarily of serum and cells, their presence on the skin surface implies that vascular and epidermal permeability has increased to permit their formation. Serum and inflammatory cells are released into the tissues from the dermal vasculature, then cross the epidermis to the skin surface either through erosions or ulcerations or by permeating between the intercellular spaces. The exudate dries on the skin surface, in combination with any medication or debris that was already present on the hair or skin, to form the visible crust. Desquamating keratinocytes may be swept up in the exudate and become part of the crusts. Bacteria frequently invade crusts after they have formed and will be noted on histologic examination, even though they may not be a factor in the pathogenesis. Fungal organisms, when present, are more likely to be important to the pathogenesis of the underlying disease process.

11.6.3 Approach to Diagnosis of Scaling and Crusting

The most important factor in determining the underlying cause of scale or crust formation in either a horse or a ruminant is to determine if the patient is pruritic and if some or all of the lesions are induced by self-trauma. If pruritus is a feature, the approach to diagnosis of pruritus should be used because all pruritic diseases can cause scale and crust formation. If the patient is not pruritic, the most important differential diagnoses include infectious diseases (particularly dermatophilosis and dermatophytosis), nutritional disorders, toxicities, autoimmune disease (pemphigus foliaceus), cutaneous filariasis, photosensitization, irritant contact reactions or

burns, and diseases of uncertain cause (for example, in equine patients, sarcoidosis, aural plaques, and primary seborrhea) (Box 11-5).[3,6] Viral diseases are important nonpruritic causes of scaling and crusting in ruminants, although they usually are associated with ulceration and erosion with involvement of the oral cavity and mucocutaneous regions.

11.7 ABNORMAL COAT LENGTH AND DENSITY

11.7.1 Definition

Abnormalities in coat length and density can be subdivided into decreased coat length and density (alopecia, hypotrichosis) and increased coat length and density (hirsutism, hypertrichosis). Hirsutism, or excessive body hair, is far less common than alopecia, which is an absence of hair from areas where hair is normally present. Alopecias are usually classified as scarring (cicatricial) or nonscarring (noncicatricial). In cicatricial alopecias the hair follicles are destroyed, and hair loss is permanent because neogenesis of the hair follicle does not occur in an adult mammal. In nonscarring alopecias the hair follicles are retained; therefore the potential for regrowth remains. Both alopecia and hirsutism may be complete or partial, diffuse or focal, and congenital or acquired.

11.7.2 Mechanisms of Development of Abnormal Coat Length and Density

A basic understanding of the dynamics of hair structure and development is essential to an understanding of the mechanisms associated with pathologic changes in coat length and density.

The hair follicle and the sebaceous and apocrine glands are epidermal appendages. The hair follicle forms during fetal development as a downgrowth of epidermal cells toward a group of mesenchymal cells that ultimately become the dermal papillae. The sebaceous and apocrine glands begin as buds of epithelium from the sides of the developing hair follicle.

Hair is composed of keratin and is the product of the hair follicle. The hair shaft is the part of the hair that emerges from the skin surface. The hair root is the part of the hair in the follicle. The hair bulb is a knob of epidermal cells that attaches the follicle to the dermal papilla. Both the hair follicle and the shaft have distinct layers. There are two types of hair follicles: simple and compound. A simple hair follicle produces a single hair. A compound hair follicle produces multiple hairs with bundles of hairs sharing a common skin opening and a single follicle down to the level of the sebaceous gland. Below the sebaceous gland the follicle branches so that each hair has its own hair bulb. Horses and cattle have only simple follicles. Goats and sheep have a mixture of simple and compound hair follicles (Fig. 11-7).[3,5]

The normal hair growth cycle is divided into three repeating stages: anagen, catagen, and telogen, with the size and shape of the follicle changing during each stage (Fig. 11-8). The amount of time a follicle spends in each phase varies with the species, breed, individual, and body region. In addition, it is influenced by factors such as photoperiod, stress, and disease. Anagen is the active phase of hair growth. Catagen is the transition stage from the growing to the resting state. Catagen is short, and the hair quickly enters the telogen phase, in which hair growth stops. As the follicle reenters anagen, a new hair grows up beside the old and dislodges it. The signal that stimulates progression from telogen to anagen is unknown.

Coat abnormalities may result from a multitude of endogenous and exogenous factors that can modify the normal pattern of hair growth and development.

The length, density, and texture of the coat of a normal animal are determined genetically, and a variety of hereditary defects result in coat abnormalities. These defects may cause changes in hair length, density, or quality. Coat quality may be abnormal at birth or may become apparent sometime before 6 months of age. A given defect may alter the number of follicles present in the skin, or the number of follicles present may be normal but there may be genetic alterations in the way the hair is produced. Altered hair production may manifest as an increased or a decreased growth rate or as structural deformities that result in weak hair shafts that break easily.

Nutritional imbalances can affect growth and maintenance of the coat in various ways, depending on the species. Nutritional deficiencies may result in a shift of greater numbers of follicles into telogen, thus increasing shedding. Dietary carbohydrate and protein deficiencies reduce the length, diameter, and strength of hair. Supplementing the diet with carbohydrate and protein releases protein for keratin formation, provides energy to use protein, and maintains mitotic activity in the hair matrix. Fatty acid deficiencies affect lipid production in the skin, leading to a dry coat with increased fragility. A variety of vitamin and mineral deficiencies may also result in poor hair growth or quality.

Inflammatory skin diseases frequently result in hair loss. Infectious inflammatory processes such as dermatophytosis and pyoderma are usually directed specifically at the hair or hair follicle. Inflammatory processes directed elsewhere may still affect the hair follicle by sweeping it up as an “innocent bystander.”

Hormonal effects on hair growth are complex. Thyroid hormones, corticosteroids, sex hormones, melanocyte-stimulating hormone (MSH), adrenocorticotropic hormone (ACTH), growth hormone, and prolactin all affect hair growth. The effect of a single hormone may be modified in the presence of other hormones, and the

importance or effect of any one hormone on hair growth may differ from species to species. Hormonal variations affect the hair coat quality and length by altering the period of time that hair follicles spend in any given part of the cycle, by influencing the rate of hair growth, and by inducing follicular atrophy. External factors such as changes in the photoperiod influence hair growth by altering hormonal levels.

Trauma to the skin is a frequent secondary cause of hair loss. Self-trauma induced by pruritus is the most common cause of alopecia. Hairs may be lost either from trauma to the hair shaft, resulting in breakage, or from trauma to the dermis, resulting in destruction of the hair follicle. In the former case, the hair regrows once the source of trauma has been removed. In the latter case, hair loss is permanent.

11.7.3 Approach to Diagnosis of Abnormal Coat Length and Density

The differential diagnosis of abnormalities resulting in *increased* coat and length density is relatively limited and does not provide much of a diagnostic dilemma for the clinician. In the horse increased coat length and density is an acquired abnormality associated with equine hyperadrenocorticism.[3] In ruminants defects are congenital and are either the result of an in utero infection (border disease) or a breed-specific hereditary defect.[5]

The differential diagnoses of *decreased* coat length and density are extensive. The initial step is to determine if the alopecia is congenital, implying a hereditary defect, or acquired. If the abnormality is acquired, the clinician must determine if it is a primary alopecia or secondary to another cutaneous abnormality such as pruritus or ulceration. If alopecia is the result of another primary cutaneous abnormality, the clinician should focus on the differential associated with that primary abnormality. Finally, to help provide a prognosis for hair regrowth, the clinician should biopsy to determine if the alopecia is scarring (cicatricial) or nonscarring (noncicatricial). Regardless of the underlying cause and its resolution, hair will not regrow with a cicatricial alopecia because by definition the hair follicle has been destroyed. In a noncicatricial alopecia the potential for hair regrowth remains if the underlying cause for hair loss can be identified and resolved (Box 11-6).

The following steps are a guide to the diagnosis of decreased coat length and density in horses and ruminants:

1 History (see Fig. 11-1)

a Determine whether the lesions are congenital or acquired. If they are congenital, determine if any related animals are affected and if the lesions have progressed since birth.

b If the alopecia is acquired, determine if the animal is pruritic and if other cutaneous lesions have been observed.

c Determine if the animal's diet is nutritionally complete.

d Determine if the animal has been exposed to any toxic substances.

e Determine if contact animals of the same or different species are affected. If contact animals are affected, a contagious problem such as dermatophytosis or dermatophilosis should be considered. Because feed and environment are also shared, dietary deficiencies and toxicities should be included in the differential diagnosis.

Increased Coat Length

- Pars intermedia pituitary dysfunction (horses)
- Congenital hypertrichosis

* Alopecia without pruritus, crusts, or other clinical signs.

f Determine what medications have been given systemically or applied topically to the patient. Use of certain topical agents, along with a history of an inflammatory stage preceding or coincident with the alopecia, may suggest a diagnosis of contact dermatitis. Administration of systemic medications may suggest that the cause is a drug hypersensitivity.

g Determine if the animal has been subjected to any stresses that might provoke a telogen effluvium.

2 Physical examination (see Fig. 11-2)

a Check for evidence of disease in organ systems other than the skin. Does the animal appear thin and malnourished, suggesting hair loss related to a dietary deficiency? Is it febrile or suffering from a severe systemic disease, suggesting a telogen effluvium?

b Can the hairs be epilated readily from the coat? If not, hair loss may be caused by trauma (self-induced or external). If so, underlying nutritional, hormonal, or stress-related causes of alopecia are more likely.

c Look for evidence of excoriation, suggesting that self-trauma is the cause of the hair loss.

d Determine whether the lesions are generalized or localized, either to particular areas of the body or to certain hair colors (e.g., black hair follicle dystrophy). Note if the hair loss has a symmetric pattern.

e Inspect the coat closely for small but grossly visible parasites such as lice or their eggs.

f Inspect contact animals for evidence of disease.

3 Microscopic examination of the ends of affected hairs (squared or broken ends suggest that the hair loss is traumatically induced; tapered ends suggest an abnormality in the hair follicle, growth cycle atrophy, or an inflammatory process such as dermatophytosis)

4 Skin scrapings

5 Acetate tape preparations

6 Dermatophyte culture and KOH preparation

7 Microfilarial preparation

8 Biopsy for routine histopathologic examination (sagittal sections should be evaluated to determine the proportion of hairs in the anagen, catagen, and telogen phases; for the presence or absence of inflammation and infectious organisms; and for evidence of scarring, which suggests a poor prognosis for hair regrowth; cross-sections of the biopsy specimen should be evaluated in noninflammatory alopecias to determine the number of hair follicles present per given area)

The following steps are a guide to the diagnosis of increased coat length and density in horses and ruminants:

1 Horses demonstrating increased coat length and density should be evaluated with appropriate laboratory tests for hyperadrenocorticism.

2 Lambs with increased coat length and density should be evaluated for evidence of border disease.

3 Cattle with increased coat length and density probably have hereditary hypertrichosis.

11.8 ABNORMAL PIGMENTATION

11.8.1 Definition

The following terms are used when discussing pigmentation and pigmentary abnormalities.[3]

- *Melanin* is a brown-black, light-absorbing, insoluble pigment formed in many organisms by specialized cells called *melanocytes*.

191

192

- *Hyperpigmentation* is an excessive tissue deposition of pigment, usually melanin.
- *Hypopigmentation* refers to less than normal pigmentation and can be congenital or acquired.
- *Leukoderma (hypomelanosis)* is a partial or total acquired loss of melanin pigment from the skin. The term *vitiligo* also refers to an acquired loss of melanin from the skin but is often reserved for a specific type of leukoderma found in humans.
- *Leukotrichia* is an acquired loss of pigment from the hair.
- *Albinism* is a congenital lack of pigment in all tissues.

11.8.2 Mechanisms of Pigmentation Abnormalities

Cutaneous pigmentation results from the interaction of melanocytes and keratinocytes. The degree of “baseline” pigmentation observed in an animal is genetically controlled. Melanocytes are of neural crest origin and migrate from this site during embryologic development. They are present in nearly all tissues but occur in the highest numbers in the epidermis, mucous membrane epithelium, dermis, hair follicles, leptomeninges, uveal tract, and retina. Epidermal melanocytes are found in the basal cell layer, and each melanocyte is presumed to supply melanin to 10 to 20 keratinocytes. Melanin is usually found in the deeper layers of the epidermis, although darkly pigmented animals may have melanin throughout the epidermal layers.

Melanocytes produce membrane-bound organelles called *melanosomes* that fuse with vesicles containing the enzyme tyrosinase. Melanin, a black-brown pigment, is produced from tyrosine in the presence of tyrosinase and copper. It is deposited on the protein matrix in the melanosomes. Once melanosomes are fully melanized, they disperse to the periphery of the dendrites of the epidermal melanocytes, and the dendritic tips are phagocytized by keratinocytes. Melanin is also synthesized and transferred to cells of the hair shaft during the anagen phase.[3]

In general, mechanisms associated with pathologic pigmentary disturbances in large animals are poorly understood. Hyperpigmentation results from increased amounts of melanin in the epidermis or dermis or both. The melanin may be present in melanocytes, keratinocytes, or melanophages (dermal macrophages that have phagocytized melanin pigment). Hyperpigmentation is an uncommon problem in horses because most normally have darkly pigmented skin. Hyperpigmentation may be reversible: with removal of the pigment-promoting stimulus, it tends to decline over time to the baseline level.

MSH may stimulate hyperpigmentation. MSH acts by affecting the levels of cyclic adenosine monophosphate (cAMP), resulting in increased tyrosinase activity. MSH also causes increased dispersion of melanosomes into melanocyte dendritic processes, where they are phagocytized by keratinocytes. Increased levels of ACTH,

estrogens, progesterones, and androgens may also have effects on pigmentation, although the importance and mode of action in large animals is not clear.

Inflammation from a variety of causes and persistent cutaneous trauma from friction induce hyperpigmentation. Stimuli that may be factors in large animals include physical cutaneous damage (trauma, friction), chemicals (primary irritants, allergic sensitizers, photosensitizers), infectious agents, and nutritional disturbances.

Hypopigmentation is the result of a decreased amount of melanin in the epidermis or dermis (or both) and may be congenital or acquired (depigmentation). Possible mechanisms include decreased melanin production (defects in melanocyte migration during embryogenesis or disorders of melanin synthesis), decreased dispersion of melanin granules (defective transfer of melanin to keratinocytes), and increased loss of melanin (accelerated desquamation of epidermal melanin, epidermal pigment loss caused by disruption of the basement membrane with resultant pigment incontinence, or immunologic destruction of melanin or melanocytes).

Several congenital genetic abnormalities that result in partial or total hypopigmentation have been identified in large animals. Albinism is a recessive condition in which a normal complement of melanocytes is present but a biochemical defect results in lack of ability to synthesize tyrosinase, so that melanin is not produced. There is complete lack of melanin in all tissues in a true albino. Pseudoalbinism, in which there is ocular pigmentation, may be more common. Other genetic disorders include abnormal melanosome production and abnormalities in melanocyte development and migration from the neural crest (piebaldism).[3,5]

Acquired hypopigmentation (leukoderma) may be caused by several factors, including genetic abnormalities, trauma, inflammation, dietary imbalances, hormonal influences, and immunologic disorders. In some cases acquired hypopigmentation is idiopathic. Juvenile Arabian leukoderma appears to have a genetic basis because of the predilection for the Arabian breed and the occurrence of the disease in young animals.[6] Trauma and inflammation are the most common factors associated with depigmentation, particularly in the horse. The intensity of the inflammatory reaction may bear little relation to the degree of postinflammatory leukoderma. Dietary abnormalities, particularly molybdenum toxicity and copper deficiency, are associated with faded or washed out coat color in food animals. Severe protein deficiency, such as occurs in kwashiorkor in humans, can lead to deficient melanin pigmentation. Melatonin is a hormone produced by the pineal gland that antagonizes MSH, thus causing decreased pigmentation, although an association with pathologic hypopigmentation in large animals has not been documented. Immunologic destruction of melanocytes has been documented in humans and is suspected of being a factor in acquired hypopigmentation in the dog but has not yet been documented in large animals. Idiopathic leukodermas are noted in all species.

Leukotrichia is the result of decreased amounts of melanin in the hair shaft. In most cases the pathogenesis is speculative, and the actual factors are unknown. Melanocytes in the hair bulbs can be affected independently of melanocytes in the epidermis, and leukotrichia without a coexistent leukoderma is common. Leukoderma, however, is usually accompanied by leukotrichia; thus, when the two conditions ae seen in combination, their pathogenesis is the same. Several leukotrichias that occur independently of leukoderma appear to be genetically induced because of breed predilections (e.g., reticulated leukotrichia of quarter horses and spotted leukotrichia of Arabians). In addition, viral infection is suspected as one of the causes of hyperesthetic leukotrichia of horses.

11.8.3 Approach to Diagnosis of Pigmentation Abnormalities

The initial approach to diagnosis of pigmentary abnormalities is to determine whether the defect is congenital or acquired. Congenital pigmentary abnormalities are almost always caused by a genetic defect, whereas acquired abnormalities most commonly do not have a hereditary basis. If the abnormality is acquired, the clinician must

determine if it is a primary pigmentary abnormality or if it is associated with some other pathologic change such as inflammation or trauma. If associated changes are a feature of the disease, differential diagnosis should focus on the initial pathologic changes (Box 11-7).

11.8.3.1.2

INCREASE IN PIGMENTATION

Pruritus

Melanoma

The following steps are a guide to the diagnosis of pigmentation abnormalities in horses and ruminants:

1 History (see Fig. 11-1)

a If the pigmentary change is congenital, determine if related animals are affected and if the lesions have progressed or regressed since birth. Take note of the patient's signalment and determine if that breed has been documented to have congenital pigmentary abnormalities.

b If the pigmentary change is acquired, determine if the animal has been subjected to cutaneous trauma that could result in posttraumatic pigmentary change. Determine if other cutaneous lesions in addition to the pigmentary changes have been observed (e.g., inflammation, ulceration).

c Determine if the animal's diet is nutritionally complete and balanced.

d Determine if the animal has been exposed to any toxic substances.

e Determine if contact animals of the same or different species are affected. Because feed and environment are shared, if contact animals are affected, dietary imbalances and toxicities should be included in the differential diagnosis.

f If the affected animal is a horse, determine what parasiticidal agents have been administered and if they are effective in the treatment or prevention of onchocerciasis.

2 Physical examination (see Fig. 11-2)

a Check for evidence of disease in organ systems other than the skin. Does the animal appear thin and malnourished, suggesting a pigmentary change secondary to a dietary deficiency or toxicity?

b If the patient's problem is hypopigmentation, examine the coat closely to determine if leukoderma, leukotrichia, or both are present.

c Look for evidence of other cutaneous lesions (inflammation, ulceration) that could result in postinflammatory pigmentary changes.

3 Microfilarial preparation

4 Biopsy for routine histopathologic examination (affected, unaffected, and marginally affected areas should all be biopsied and labeled appropriately for histologic comparison).

John Maas

13.1 LAMENESS AND STIFFNESS

***Randall B. Eggleston*,**

***John Maas*,**

Lameness, is the term used to describe a condition in which an animal is incapable of normal locomotion. Generally lameness is characterized by an inability to maintain a normal gait, manifested by asymmetry in movement, apparent incoordination or weakness, and inefficient or ineffective motion of the limbs. Lameness usually can be assessed only when the animal is moving under its own power, although lameness severe enough to cause an inability to bear weight can be assumed at a standstill. The onset of lameness can be acute (e.g., fracture), chronic (e.g., degenerative joint disease), or acute on chronic (e.g., catastrophic fracture secondary to stress fractures).

13.1.1 Mechanisms of Lameness and Stiffness

The ultimate effects of any cause of lameness are restricted movement of the limbs or body, reduced performance, and abnormal gait. Causes of lameness are generally associated with conditions of the musculoskeletal system or nervous system. Most causes of lameness have both a musculoskeletal component (e.g., atrophy of the supraspinatus and infraspinatus muscles) and a neurologic component (e.g., suprascapular neurapraxia). Some causes of lameness have only a musculoskeletal component (e.g., upward fixation of the patella) and are not principally associated with either afferent nerve signs (i.e., pain) or efferent nerve signs (i.e., motor dysfunction). Similarly, other causes of lameness are solely related to a motor nerve deficit (e.g., radial neurapraxia).

Unlike the usual definition of lameness, “stiffness” refers to a generalized restriction in freedom of movement in a limb, the neck, or back. Stiffness is manifested by a limited range of motion by a joint, reduced length of stride, or decreased flexibility during bending or turning. For example, cellulitis and soft-tissue swelling in the area of the tarsocrural joint can cause restricted freedom of movement of the hindlimb and an apparent lameness, yet there may be no specific musculoskeletal or neurologic cause. Stiffness may have either congenital or acquired causes, and the clinical signs may be mild and transient or severe and persistent. Stiffness may or may not be associated with pain.

13.1.2 Approach to Diagnosis of Lameness and Stiffness in Horses

The lameness examination is the most commonly performed assessment of the musculoskeletal system in the horse. The examination should be well planned, consistent, and thorough. Knowledge of all diseases capable of causing lameness is not required, as long as the examiner maintains an open mind and objectivity during the examination (Box 13-1). The goals of the lameness examination are to determine which limbs are affected, differentiate between supporting limb and swinging limb lameness, and to establish the musculoskeletal and/or neurologic components producing the lameness.

1 History. The lameness examination begins with the client interview. A summary of the important historical features of the lameness should include answers to basic questions about the following:

- Onset (e.g., When was the last time the horse was seen sound? Was the lameness acute in onset, or did it have a slow, insidious onset?)
- Characteristics of the lameness (e.g., Is the lameness seen more in hand, at the lunge, or under saddle?)
- Associated or inciting factors (e.g., injury) that may have contributed to or caused the lameness
- Changes in the characteristics, intensity, and duration of the lameness
- Responsiveness to treatment (e.g., Has the horse received any type of treatment, and if so what was the response?)
- Time since the last hoof trimming and shoeing, and whether or not the horse's shoeing was changed

In addition, the signalment and the activity that the horse undertakes (e.g., jumping vs. racing) should be ascertained and may be a guide in determining potential causes of the lameness (e.g., stress fractures are more common in racing thoroughbreds, and osteochondrosis is more commonly diagnosed in young animals).

2 Observe from a distance—stationary phase. Observing the horse from a distance while it is stationary permits an assessment of the horse's conformation, position, and posture. The horse should be viewed from the front, from behind, and from both sides. From the front, special note should be made of any abnormality in the following: *217*

218

- Conformation. A number of conformational abnormalities have been associated with lameness (e.g., upright pastern conformation predisposes to pastern disease and foot lameness; offset or bench knees predispose to carpal disease; and straight through the hocks or postlegged conformation predisposes to upward fixation of the patella, suspensory desmitis, and fetlock disease). Poor conformation can affect the young horse when it is put into training or can cause a slow insidious onset of lameness. Recognizing these conformational abnormalities at the time of examination can be helpful in diagnosing potential causes of lameness. When a horse is evaluated for purchase, recognition of poor conformation should be noted and discussed as a source of future lameness problems.

COMMON CAUSES

Infections of the foot

Bruised or punctured sole

Hoof wall defects

Fractures

Septic (infectious) arthritis

Laminitis

Secondary (degenerative) joint disease

Navicular disease

Osteomyelitis

Fibrotic or ossifying myopathy

Rhabdomyopathy (tying up)

Sprain

Strain

Tenosynovitis

Contracted tendons (flexural deformity)

Ankylosis or arthrogryposis

Osteochondrosis or bone cyst

Cruciate or meniscal rupture

Luxation or subluxation (dislocations)

Upward fixation of the patella (locking patella)

Sesamoiditis

Muscle injury, soreness, bruise, trauma, compartment syndrome

Subcutaneous abscess, cellulitis

Angular limb deformities

Disruption of the suspensory apparatus (broken down)

Postanesthetic equine myasthenia

Tendon rupture, damage, tendonitis (bowed tendon)

Osteomalacia, osteodystrophy (rickets)

Bucked shins

Epiphysitis (physeal injuries)

Purpura hemorrhagica

POISONS, TOXINS, DEFICIENCIES, AND EXCESSES

Moldy sweet clover poisoning

Strychnine toxicity

Tetrachlorodibenzodioxin (dioxin) toxicity

Warfarin (Dicumarol) toxicity

Vitamin K—induced renal toxicity

Calcinosis resulting from plant poisoning

Zinc toxicity

Phosphorus toxicity

Phosphorus deficiency

Vitamin D toxicity

Locoweed-associated limb deformities or stringhalt-like gait

Chronic fluoride toxicity

- Position of the head (e.g., tilted, turned)
- Distribution and equality of muscle mass along the neck and trunk
- Topographic symmetry of the front limbs, from the dorsal region of each scapula to the hoof

From the rear, the height and mass of the hip musculature and the symmetry between the hindlimbs should be assessed. From each side, abnormalities in stance (e.g., camped out in front) or load bearing (e.g., dropped elbow) and the position of the head and neck (e.g., hyperflexed poll) should be compared.

3 Physical examination and palpation. Palpation enables a closer inspection of the horse and identification of abnormalities that may or may not otherwise be noticed. A thorough examination of the musculoskeletal system not only allows for identification of palpable abnormalities but also offers the opportunity for the practitioner to refine the identification of normal structures; subtle abnormalities cannot be appreciated unless the examiner is skilled at recognizing normal anatomy. There are also many instances in which normal structures palpate abnormally but are not necessarily associated with lameness (e.g., flexor tendon sheath [windpuffs, windgalls] and palmar or plantar MCPJ pouch effusion [wind puffs]). The examination should be conducted consistently and thoroughly starting with the cervical neck and concluding at the tail. Abnormal findings should be described to identify their location on the limb, their size, and their orientation relative to normal anatomic landmarks.

218

219

Palpation of the upper limb is often limited to the overlying muscle mass, with an identification of any atrophy, hypertrophy, pain, or fibrosis. Articular structures and surrounding ligamentous structures can be difficult to palpate because of the overlying muscle. Deep palpation of the thoracolumbar and gluteal musculature can provide clues to potential hindlimb lameness and tack or rider issues. The pelvis, iliac

arteries, and sublumbar musculature can be evaluated by rectal palpation while the horse is standing quietly; movement or crepitation can be assessed while swaying the horse from side to side.

Particular attention should be directed toward palpation of the limbs. The majority of lameness will originate from the carpus distally in the front limb. Common sources of lameness in the hindlimb can be identified from the stifle distally. All palpable structures should be evaluated, including skeletal structures, synovial structures (joints, tendon sheaths, and bursa), and soft-tissue structures (tendons and ligaments). This portion of the examination can be performed using different methods, either by palpating each tissue in one pass of the limb or by making multiple passes of the limb, palpating each tissue structure separately. Regardless of the preferred technique, a consistent and complete examination should be performed. Once the limbs have been palpated in the weight-bearing position, the examiner should palpate them in the non—weight-bearing position. This allows for separation of the soft-tissue structures and facilitates deep palpation of the suspensory apparatus. Comparing limbs is often useful for distinguishing an abnormality from an unusual or unique conformation.

The relative size, shape, and condition of the feet (e.g., contracted heel, scuffed toe), length of heel, and pattern of shoe wear (e.g., thinner branch on the outside of the shoe than on the inside) give clinically significant but often overlooked clues to the site and cause of lameness. Evaluation of the feet with hoof testers is mandatory; most lameness arises from problems in the forefeet.

Certain signs indicating trauma (e.g., wounds, swelling, hair loss, pain) may lead to more important findings such as underlying evidence of a fracture (e.g., bony crepitus, warm or cold areas, bony protuberance).

4 Observe from a distance—mobile phase. Observations made from a distance while the horse is moving can be evaluated critically once clues provided by the history, and observations made of any postural deformities, direct the practitioner's attention to a specific area of the horse's body. This part of the examination is conducted while the horse is moving in at least two gaits, the walk and the trot. Sometimes it is also helpful diagnostically to observe the horse move at other gaits (e.g., canter) or while under saddle. It may also be beneficial to observe the horse on different surfaces (hard and soft) to amplify different lamenesses. If possible, the horse should be evaluated under similar conditions as that under which it performs.

At a walk the horse should be observed moving toward and away from the examiner. The break-over point of the foot at the toe, the arc of the foot flight, the distance covered by the foot in the swing phase, and the placement of the foot should be evaluated for each limb and should be compared between pairs of limbs. Although many abnormalities often can be observed only during a trot, some conditions may cause a subtle alteration in gait that can be observed only at a walk (e.g., fibrotic myopathy).

If a fracture is suspected (e.g., nondisplaced long-bone fracture) or if there is the possibility of exacerbating preexisting trauma, this part of the examination should either be abbreviated or not performed at all to preclude further damage or trauma. In such cases, immediate radiographic or other definitive diagnostic tests should be performed (Box 13-2).

Recognizing the asymmetric movement of the head and neck for frontlimb lamenesses, and the asymmetric movement of the pelvis for hindlimb lamenesses, is a common method of lameness identification. Hindlimb lamenesses often present the greatest challenge.

Sound horses at a trot show a perfect sinusoidal pattern for all midline body locations including the head, withers, and tuber sacrale. The height of these structures falls from the beginning of the diagonal stance phase, reaching the lowest position at mid stance, then rising to the highest level at or shortly after the end of the stance phase (suspension). Correlating head and neck movement with the correct front limb lameness is relatively easy. It is well recognized that the head is elevated during the stance phase of the lame limb, with an increase in downward motion during the stance phase of the sound limb—"down on sound." Lameness can also be recognized by changes in the distal limb, including changes in the motion of the metacarpophalangeal joint (MCPJ). During the stance phase, the hyperextension of the MCPJ is decreased with increasing lameness in the lame limb, whereas in the contralateral sound limb an increase is seen. With respect to stride length and foot flight, with forelimb lameness the caudal phase of both the lame and the sound limbs becomes shortened whereas the cranial phase remains unchanged. In the hindlimbs the opposite is seen; the cranial phase is shortened and the caudal phase remains unchanged. This may be explained by the significantly decreased suspension phase following the lame diagonal. In the forelimbs the arc of the lame front foot is unchanged, but there is an increase in the arc of the sound front foot. In the hindlimbs, the arc of the foot flight in the lame hindlimb is lower than the sound limb in most cases. The change in maximal hoof height during the swing phase appears to be the result of changes in trunk height and is no indication for reduced flexion in the upper joints or an effort to reduce the pain when the hoof lands. Medial (winging) or lateral (paddling) deviation of the distal limb during the flight phase can result in interference and trauma to other limbs and potential lameness. Conformational abnormalities, most commonly, toeing-in or toeing-out, give rise to an alteration in the point of break-over and a change in the flight of the distal limb. Poor foot balance caused either by poor conformation or by poor trimming can result in similar flight patterns.

Plaiting, describes adduction of the lame limb directly in front of or lateral to the opposite limb. In the front limbs, plaiting is commonly the result of faulty conformation, but in the hindlimbs it is more commonly associated with lameness. This pattern of travel is often associated with upper limb lameness but can also be seen with distal hock or high suspensory disease.

A dampening effect also appears to occur as an adaptation to lameness. This effect is more pronounced in the hindlimb than in the frontlimb. Flexion of the shoulder and hock joints actually increases during weight bearing in the lame limb. This is probably an increase in the function of the shock-absorbing mechanism. The increased flexion cannot be related to increased loadings but has to be attributed to a gentler braking of the flexion by the extensor muscles. In such a way, the loading of the lame limb with the body weight occurs more gradually, reducing the peak forces in the hoof.

The tuber coxae are typically the landmark of choice in evaluating hindlimb lamenesses. Because the tuber coxae are more laterally located, the pattern is different from that seen in the head. Also, because the hindlimbs lack closely located segments, such as the neck and head, an enhancement of the vertical movements must be found in a rotation of the back around a longitudinal axis. Such a rotation is indicated by different vertical displacements of one tuber coxae during both stance phases. The vertical movement of the tuber coxae exhibits a characteristic pattern of a double-waved, slightly asymmetric line during one stride. The lowest point of the hip is reached in the middle of the stance phase of the right contralateral limb. The highest point of the hip is reached shortly after the stance phase of the contralateral limb, just before the stance phase of the left hindlimb.

Kinematic studies have more clearly defined the notion of “hip hike,” and “hip drop” and have recorded regular patterns of pelvic movement in lame horses. Consistent findings in the overall pelvic movement in the lame horse include less downward movement during the midstance phase and less upward movement at the end of and after the stance phase of the lame limb. This can give the appearance of an overall pelvic elevation during the stance phase of the lame limb as compared with pelvic height during stance of the sound limb; a similar exaggerated pattern is seen in the tuber coxae. The tuber coxae also exhibit less downward movement during the midstance phase and less upward movement at the end of the stance phase in the lame limb. More notably, there is more downward movement during midstance of the sound limb (midflight of the lame limb), and more upward movement at the end of stance of the sound limb (impact of the lame limb), giving rise to the notion of a “hip hike.” These changes result in an increase in the overall vertical movement of the tuber coxae on the lame side as compared with the sound side. Clinically, many find it easier to identify the exaggerated excursion of the tuber coxae to identify the side of the lameness.

Lateral movement or drifting of the hindend can also be seen in horses with unilateral hindlimb lameness. Horses tend to drift or move away from the side of the lameness. Subtle lameness with an absence of asymmetric pelvic movement may present with a consistent drifting to one side or the other.

Thorough and useful systems for grading the severity of lameness are available. Most systems are designed to enable the practitioner to compare how lameness changes with time, assess the characteristic of lameness among horses, and accurately record information and communicate information to other veterinarians. Simple and consistent schemes that are easy to remember and modify can be developed (Table 13-1).

Once the initial standing and mobile examinations are completed and the affected limb is identified and the lameness graded, isolating the specific region of the limb is the next goal of the lameness examination. Manipulative tests or stressing of articulations and associated soft-tissue structures can provide additional information as to the location of the source of lameness. Flexion and extension tests are designed to stress selective regions of the limb and observe the effects of the manipulation on the lameness. These tests are also commonly performed on the sound horse to reveal potential areas of concern particularly during prepurchase examinations. Flexion and extension manipulations also enable an assessment of range of motion. Interpretation of these tests should be approached with caution. They are seldom specific for one particular joint. For example, the fetlock flexion test not only stresses the fetlock joint but also places stress on the proximal and distal interphalangeal joints; the hock flexion test also flexes and stresses the stifle joint because of the presence of the stay apparatus. If a flexion tests results in a positive response, the horse should be walked out of the response and observed before additional manipulations. Occasionally exacerbation of the lameness will persist for an extended period of time, which changes the baseline lameness and clouds the interpretation of additional manipulations.

It is common for horses to be presented with multiple lamenesses. Secondary lameness or compensatory lameness is the result of increased stress or overloading of the other limbs in response to the primary lameness. This most commonly occurs in the contralateral limb but can also occur between front limbs and hindlimbs. The secondary lameness can also be the result of shifts in body mass that produce an apparent or phantom lameness. Phantom lameness is less severe than the primary lameness. The following guidelines can be used to aid in the differentiation between a real or compensatory and an apparent or phantom lameness.

- Address most severe lameness first.

- Horses with primary hindlimb lameness and apparent or phantom contralateral frontlimb lameness. Each lameness should be considered as real.

Table 13-1 A Five-Grade Lameness Scheme

Grade	Description
1	An inconsistently observable lameness visible under special circumstances (in a circle, flexion tests, hard surface, etc.)
2	A consistently observable lameness visible only under special circumstances (in a circle, flexion test, hard surface, etc.)
3	A consistently observable lameness at a trot in a straight line
4	A consistently observable lameness at a walk
5	A non—weight-bearing lameness; horse is unable to use the leg
Modified from the *American Association of Equine Practitioners Newsletter*, March:12, 1983.	

220

221

- Horses with a primary forelimb lameness and apparent or phantom ipsilateral hindlimb lameness. Each lameness should be considered as real.
- Primary forelimb lameness may produce asymmetric pelvic movement causing the perception of a contralateral hindlimb lameness. Example: left foreleg lameness (head elevation) causing apparent or phantom right hindleg lameness (hip drop).
- Horses with a primary forelimb lameness and apparent contralateral hindlimb lameness. Block out frontlimb lameness first.
- Primary hindlimb lameness (≥3 to 5/5) can mimic ipsilateral forelimb lameness. Example: A horse shows a cranial load shift during the stance phase of lame limb that causes the head and neck to shift forward and nod down, giving the perception of ipsilateral lameness—"down on sound."
- Horses with a primary hindlimb lameness and apparent ipsilateral forelimb lameness. Block out the hindlimb lameness first.

Assumptions as to the cause of a horse's lameness based solely on the physical examination and visual inspection should be avoided unless obvious signs, for example severe swelling or crepitus, are present. After the physical and visual examination, evaluation of the horse with diagnostic analgesia is mandatory for the accurate isolation and diagnosis of equine lameness. A thorough knowledge of anatomy and the structures desensitized by blockade of the appropriate peripheral nerves or synovial structures is essential (Table 13-2). *When performing perineural analgesia it is important to remember to block from distal to proximal*., An improvement in gait indicates a favorable response to a nerve or joint block; complete elimination of gait asymmetry is unusual and generally should not be expected after intraarticular or peripheral nerve analgesia. If necessary, improvement in gait can be confirmed by repeating the successful block the next day. By that time residual effects from multiple blocks performed previously should be absent.

Common local anesthetics used in horses include 2% solutions of lidocaine, mepivacaine, and bupivacaine. These solutions all share a common mechanism of action, specifically the ability to block or inhibit nociceptive nerve conduction by preventing the increase in membrane permeability to sodium ions. Lidocaine and

mepivacaine are considered to be fast acting and have a duration of action of 1½ to 3 hours and 2 to 3 hours, respectively. Bupivacaine on the other hand is intermediate in onset and has a much longer duration of action of 3 to 6 hours. Mepivacaine is reportedly less irritating to tissues than lidocaine.

Table 13-2 Structures Desensitized by Commonly Performed Nerve Blocks

Nerve Block	Nerve(s) Affected	Structures Desensitized*
Palmar (plantar) digital	Palmar (plantar) digital	Heel bulbs; frog; bars; navicular bone and bursa; palmar regions of the third phalanx, distal interphalangeal joint, sole, and soft tissues
Abaxial sesamoid	Palmar (plantar)	Coronary band, interphalangeal joints, lamellar and solar corium
Low palmar (volar)	Palmar, palmar metacarpal†	Skin of medial and lateral pastern, metacarpophalangeal joint, proximal sesamoids, flexor tendons, tendon sheath
High palmar (volar)	Palmar, palmar metacarpal†	Skin and deep structures of palmar cannon region (flexor tendons, suspensory ligament except origin, interosseous ligaments of splint bones)
High two-point	Lateral palmar, medial palmar	Origin of suspensory ligament

* Includes all structures listed up to and including the particular block; first structure listed in each block is also the area that can be tested with point pressure to evaluate the effectiveness of the block.

† For hindlimbs, additional anesthetic (i.e., ring block) is needed at the level of the particular perineural block to achieve the desired effect.

Intrasynovial analgesia can be used to more specifically isolate a lameness to a joint, tendon sheath, or bursa. It can be used in combination with perineural analgesia or alone depending on the suspected source of the lameness. Proper patient restraint and strict aseptic technique including aseptic preparation of the skin, wearing sterile gloves, and use of a new bottle of anesthetic are imperative to avoid iatrogenic synovial sepsis. Lameness may be erroneously associated with a joint if intraarticular analgesia of several joints is performed within a short period of time; ample time (30 to 60 minutes) must be allowed between joint blocks to allow for adequate articular desensitization.

When performing intrasynovial analgesia it is not necessary to follow the distal to proximal rule. If intraarticular analgesia of a proximal joint results in no improvement in the lameness, immediate follow-up with distal limb perineural blocks is still possible. Exceptions to this rule exist with intrasynovial analgesia to the foot. When performing intrasynovial analgesia of the distal interphalangeal joint (DIPJ) or navicular bursa, it is important to take into consideration the volume of anesthetic used and the timing at which the lameness is reevaluated. The recommended volume of anesthetic for the DIPJ is 4 to 5 mL, and for the navicular bursa 3 to 4 mL. Once injections into these structures have been performed, the horse should be evaluated at 5-minute intervals to help with the interpretation of the response to the block.

Significant improvement in experimentally induced lameness to the navicular bursa can be seen at 5 minutes after intraarticular anesthesia of the DIPJ with 5 mL of 2% mepivacaine hydrochloride. Amelioration of bursal lameness is mostly likely caused by diffusion of the anesthetic into the bursa via an indirect or functional communication, or by diffusion of anesthetic into the periarticular tissues. The proximal palmar pouch of the

DIPJ lies in close proximity to the palmar digital (PD) neurovascular bundles as they course along the medial aspects of the collateral cartilages, making it possible for anesthetic diffusion to block nerve conduction at that level.

Experimentally induced solar toe pain can also be ameliorated by intraarticular blockade of the DIPJ with 10 mL of mepivacaine hydrochloride. The structures innervated by the deep branch of the PD nerves include the DIPJ, navicular bursa, distal navicular ligament, laminar corium, and corium of the sole. The DIPJ capsule contacts the PD neurovascular bundle, and a local anesthetic injected into the DIPJ likely desensitizes the PD nerves below the level of the coronary band, and the structures innervated by them.

Variable responses are also seen with blockade of the DIPJ when different volumes of anesthetic are used. Blocking the DIPJ with 6 mL of mepivacaine (Carbocaine) results in significant improvement in lameness originating from the dorsal margin of the sole; however, lameness originating from the palmar sole shows no improvement. Using 10 mL of Carbocaine reduces lameness originating from the dorsal margin of the sole, as well as the palmar heel regions of the sole, but only after 30 minutes. The difference in response to analgesia of the DIPJ in attenuating pain at the dorsal margin of the sole versus the angles of the sole may be because these regions are innervated by different branches of the PD nerve. This may help distinguish between pain arising from the DIPJ or the navicular apparatus and palmar solar pain.

221
222

In contrast to the responses seen with blocking the DIPJ in the presence of navicular bursa disease, blocking the navicular bursa with 3.5 mL of mepivacaine hydrochloride in the presence of experimentally induced DIPJ lameness results in a significant improvement in lameness but only after 30 minutes. Experimentally induced lameness from the dorsal sole is improved by blockade of the navicular bursa; lameness originating from the palmar sole does not show significant improvement.

Knowledge of the previously described responses to intrasynovial analgesia of the DIPJ and the navicular bursa is helpful in localizing and interpreting lameness commonly seen in the horse. The anatomy and close approximation of the associated nervous and synovial structures of the foot give rise to a diffusion gradient associated with perisynovial infiltration of local anesthetic to peripheral nerves and variable responses to intrasynovial analgesia. Similar responses can be encountered with intraarticular analgesia of the carpus and distal tarsal joints. Instillation of anesthetic into the middle carpal joint and the tarsometatarsal joints can result in desensitization of the proximal suspensory ligament, a common site for soft-tissue injury and lameness in the horse.

Once the lameness has been described and localized, a radiographic or ultrasonographic examination can be performed as the next step to confirm a clinical diagnosis. Radiography should be performed using proper technique, an ideal film/screen combination, and multiple views to construct a thorough study (Table 13-3). Comparing radiographs of affected and unaffected limbs can help confirm or refute a suspected abnormality, evaluate the severity of the disease, and identify possible bilateral limb involvement.

Although standard radiographic techniques are well documented and described, ultrasound is becoming more and more popular and useful in musculoskeletal imaging. Indications for ultrasonographic evaluation of a lameness include diagnosis of soft-tissue injuries, including muscular, vascular, tendon, tendon sheath, ligament, joint capsule, or bursal defects; evaluation of articular surfaces (articular cartilage thickness, osteochondritis dissecans lesions); assessment of fluid accumulation (synovial effusions, seromas, or sepsis); evaluation of bony surfaces; monitoring of the progression of healing; and monitoring of the effects of training on soft-tissue injuries such as tendonitis or desmitis.

When radiographic or ultrasonographic techniques are nondiagnostic, other methods such as thermography, nuclear scintigraphy, treadmill evaluation, computerized videographic gait analysis, force plate evaluation, computed axial tomography (CAT), or magnetic resonance imaging (MRI) may be useful. University hospitals and major regional referral centers are often the only locations where these adjunctive procedures can be performed because the procedures are expensive and technically complex and they require specialized equipment and experienced personnel. However, even these techniques have limitations; for example, nuclear scintigraphy may not identify the origin of an insidious (e.g., osteochondrosis) or chronic lameness as successfully as an acute lameness.

Table 13-3 Recommended Radiographic Views of Extremities

Radiographic Series	Minimum Radiographic Views
Distal extremity (navicular)	45 degrees DP, 65 degrees DP (2), LM, flexor tangential*
Pastern	45 degrees DP, LO, MO, LM
Fetlock	45 degrees DP, LO, MO, LM, flexed LM
Metacarpal or metatarsal	DP, LO, MO, LM
Carpus	DP, LO, MO, LM, flexed LM, flexed skylines (distal radius, proximal and distal rows of carpal bones)
Tarsus	0 degrees DP, 10 degrees DP, LO, MO, LM
Radius-ulna or tibia-fibula	Cr-Cd, LO, MO, LM
Elbow	Cd-Cr, LO, LM, patellar (delete patellar)
Shoulder	ML
Stifle	Cd-Cr, LM, flexed LM, Cd 30° L-CMO, patellar skyline

Cd-Cr, Caudocranial; *Cd 30,° L-CMO*, caudal 30-degree lateral-craniomedial oblique; *Cr-Cd*, craniocaudal; *DP*, dorsopalmar (dorsoplantar); *LM*, lateromedial; *LO*, lateral oblique; *ML*, mediolateral; *MO*, medial oblique.

* View to highlight the flexor cortical margin of the navicular bone (50 degrees proximal palmaropalmaro distal oblique).

13.1.3 Approach to Diagnosis of Lameness and Stiffness in Ruminants

1 History. An accurate history is the first step in reaching a correct diagnosis of the cause of lameness in ruminants (Box 13-3). For example, although stiffness can occur at any time in life, it occasionally occurs at birth (e.g., arthrogryposis); therefore acquired and congenital signs can be differentiated on the basis of a complete history. Furthermore, other ruminants on a property may demonstrate similar clinical signs, and the onset and duration of signs may be important diagnostically. It also is useful to examine the environment and determine how the ruminant could have been traumatized or injured. Finally, any evidence of systemic disease manifested by fever, anorexia, or depression should be determined.

2 Observe from a distance—stationary phase. Next, the ruminant should be observed standing to assess posture and stance. For example, a cross-legged stance may indicate an abnormality of the medial claw of the hoof. A dairy cow with painful heels in the hind feet may stand with its heels over the gutter while in a stanchion. Alternatively, a ruminant resting its feet farther forward than usual may have a painful toe region. Small ruminants with problems in both front feet may attempt to move around on their carpi.

3 Observe from a distance—mobile phase. In ruminants these observations are usually made while walking rather than trotting the animal. This enables the examiner to identify the affected limb; to determine whether the lameness is a supporting-leg or swinging-leg lameness; and to assess how much of the lameness is solely mechanical and how much is associated with pain.

4 Palpation. The most important part of lameness examination in ruminants is examination of the foot. As with horses, most lameness in ruminants involves the foot. The examiner should look closely between toes, around the coronary band, and at the hoof wall. The sole should be pared with a hoof knife to identify discoloration or draining tracts beneath the sole or into the corium. A black discoloration may indicate infections of deeper structures of the foot. Applying pressure to the sole with a hoof tester or tapping over the wall may elicit pain. 222 223

The limb should also be palpated to detect swelling, heat, or soreness, which may indicate inflammation from infection or soft-tissue trauma. Crepitation found by manipulating the limb may indicate a fracture or dislocation. Stiffness or pain on joint flexion may indicate joint disease, either septic or degenerative.

Flexion tests and nerve blocks are not used for diagnosis as routinely in ruminants as they are in horses, but they may be useful in certain instances. The technique is similar to that described for horses, but the location of the nerves is different. Radiographs are not necessary in most cases, although they can identify bony or articular lesions that may not be readily apparent or palpable. Examination of synovial fluid obtained by arthrocentesis can be used to differentiate septic from traumatic arthritis.

13.2 POSTURAL DEFORMITIES

***Carter E. Judy*,**

***John Maas*,**

A postural deformity in horses or ruminants is an abnormal stance caused by neurologic deficit, pain, or a musculoskeletal problem. Postural deformities can range from subtle conformational faults such as broken forward foot axis to severe and unusual positions, such as when the animal is camped out in front. Inability to bear weight on a limb, asymmetric angles between joints, and lateral or medial deviations in the alignment of limbs are examples of postural deformities. Often the postural deformity itself is specific for certain diseases and conditions (Table 13-4).

13.2.1 Mechanisms of Postural Deformities

Postural deformities can be either congenital or acquired and result from maldevelopment, trauma, or disease (Box 13-4). Congenital deformities may be caused by tendon contracture or laxity, osseous malformation, and hypoplasia or aplasia of osseous structures or soft tissues. Acquired deformities are most often caused by trauma or disease. Disuse atrophy secondary to an unrelated musculoskeletal abnormality can result in abnormal posture. 223 224

Occasionally diseases affecting proprioception and consciousness may cause an abnormal stance that appears as a postural deformity (e.g., head pressing) but is unrelated to neurologic pain or a musculoskeletal problem.

Table 13-4 Examples of Postural Deformities and Possible Origins

Postural Defect	Likely Site of Origin
Contracted heels	Foot; flexor tendons
Bucked knees	Suspensory ligament
Dropped elbow	Motor nerves to forelimb; olecranon
Tiptoe stance	Foot; flexor tendons; interphalangeal joints
Non—weight-bearing	Foot; any long bone; any limb articulation
Broken down (hyperextension) fetlock; dropped fetlock	Suspensory apparatus
Toe-out hindlimb and elevated hip	Coxofemoral joint; femoral neck
Basewide behind	Coxofemoral joint; femoral neck
Hyperextension of stifle and hock	Patella
Camped out in front	Bilateral forefeet
Carpal valgus	Distal metaphysis, physis, epiphysis, or carpal bones
Stiffly elevated head	Withers; cervical spine
Shifting weight between forefeet	
Recumbency	Any long bone; feet; spinal cord; myopathy

13.2.2

Approach to Diagnosis of Postural Deformities in Horses

A history can help the examiner determine if a postural deformity is congenital, as with arthrogryposis, or acquired. Because most postural deformities in horses arise from traumatic injuries or overuse, a complete lameness examination is essential. Occasionally a postural deformity does not cause lameness; in these instances the veterinarian must consider nontraumatic causes associated with abnormal development, improper nutrition, and seemingly unrelated disease such as carpal valgus deformity.

13.2.2.1

Box 13-3 Causes of Lameness and Stiffness in Ruminants

13.2.2.1.1

COMMON CAUSES

Infections of the foot

Hoof defects

Interdigital dermatitis (infectious foot rot)

Underrun heel

Papillomatous digital dermatitis (foot warts)

Rusterholz ulcer, granuloma of sole

Laminitis

Corkscrew claw and other growth abnormality

Interdigital fibroma

Overgrown feet

Bruised or overworn sole

Puncture wound

Septic infectious arthritis

Contracted tendons

Arthrogryposis

Chlamydial arthritis of sheep

Caprine arthritis-encephalitis in goats

Fractures

Blackleg

Muscle abscess

Mycoplasma polyarthritis of sheep and goats

Osteomyelitis

Ruptured anterior cruciate ligament

Ligament rupture (e.g., torn collateral ligament of stifle)

13.2.2.1.2

LESS COMMON CAUSES

Erysipelothrix, arthritis

Vesicular stomatitis

Secondary (degenerative) joint disease

Luxations and subluxations

Sprain

Strain

Hygroma

Spinal abscess

Spinal lymphosarcoma

Osteomalacia

Bluetongue virus in sheep (coronitis and myopathy)

Dorsal fixation of the patella (bovine)

Septic tenosynovitis

Angular limb deformities

Malignant edema

Malignant catarrhal fever

Muscle injury

Ruptured tendon

13.2.2.1.3 UNCOMMON CAUSES

Sporadic bovine encephalomyelitis

Ulcerative lymphangitis

Salmonellosis

Dactylomegaly in shorthorn cattle

Bovine virus diarrhea (coronitis)

Physeal injuries (epiphysitis)

Clotting factor deficits

Hyperparathyroidism

Phycomycosis

Neoplasia

Angioneurotic edema

Hemimelia (radial, tibial, ulnar, hypoplasia, or agenesis)

Melioidosis (exotic)

Ibaraki disease (exotic)

Ephemeral fever (exotic)

African bovine malignant catarrhal fever (exotic)

Akabane disease (exotic)

Foot-and-mouth disease (exotic)

Lumpy skin disease (exotic)

13.2.2.1.4 POISONS, TOXINS, DEFICIENCIES, AND EXCESSES

Nutritional myodegeneration (white muscle disease selenium deficiency)

Fescue foot (ergot poisoning)

Congenital

Crooked calf syndrome (lupinosis)

Syndactyly

Hemimelia (radial, tibial, ulnar hypoplasia)

Osteogenesis imperfecta

Dactylomegaly in Shorthorns

Contracted tendons

Idiopathic deformities

Angular limb deformities

Shortened long bones (acorn calves)

Acquired hoof wall defects

Infections of the foot

Secondary contracted tendons

Muscle atrophy caused by denervation

Fractures

Luxations

Severed or ruptured tendons

Septic arthritis with ankylosis

Arthritides (e.g., mycoplasma, caprine arthritis-encephalitis, septic arthritis)

Osteomalacia

Rickets

Epiphysitis

Septic tenosynovitis

Chronic laminitis

Degenerative joint disease

Hypertrophic osteopathy

Hyperparathyroidism

Osteomyelitis

Ruptured gastrocnemius (goats)

Ruptured peroneus tertius

Upward fixation of the patella (locking patella)

13.2.2.3.2 POISONS, TOXINS, DEFICIENCIES, AND EXCESSES

Primary copper deficiency or secondary copper deficiency (molybdenosis) (e.g., physitis, spontaneous fractures)

Selenium poisoning

Fluoride poisoning

Phosphorus deficiency

Monensin toxicity

Calcinosis caused by plant poisoning

Locoweed-associated limb deformities

Diagnosis of the cause of a postural deformity begins with a detailed description of the deformity and assessment of the position and asymmetry of the anatomic structures involved. If the nature and severity of the deformity cannot be determined by direct observation, palpation and manipulation of the affected structure are required. Radiography and ultrasonography also can assist in the diagnosis and provide information on which to base treatment recommendations and prognosis.

13.2.3 Approach to Diagnosis of Postural Deformities in Ruminants

Because of the many differences in husbandry and management practices between ruminants and horses, most postural deformities in ruminants are congenital or arise from dietary nutritional imbalances or plant poisonings

(Box 13-5). Traumatic injuries play a smaller role, except in dairy cattle, which commonly slip on concrete and injure themselves. History, visual inspection, manipulation, and palpation are important in the diagnosis of postural deformities in ruminants. In addition, other ruminants in the herd with similar abnormalities should be identified. Plant, feed, soil, and water samples should be taken to identify toxins that may have been ingested, resulting in the deformity. Often the signalment helps rule out certain breed- or species-specific genetic defects. Because goats jump off heights, they are subject to numerous fractures, sprains, and luxations, including unilateral or bilateral rupture of the gastrocnemius tendon.

13.3 SWELLINGS AND ENLARGEMENTS (SOFT AND HARD TISSUE)

***Carter E. Judy*,**

***John Maas*,**

Swellings and enlargements consist of soft tissue (e.g., tendon) or hard tissue (e.g., osseous) and can occur anywhere on an animal's body. Generally, clinically significant swellings and enlargements associated with the musculoskeletal system occur on the limbs.

Swellings and enlargements can be further divided into two principal groups, depending on whether or not they are associated with a specific anatomic structure. For example, a soft fluctuant swelling in the region of the left carpus may be caused by an abnormality of the antebrachialcarpal joint (e.g., septic synovial effusion) or may not involve the joint at all (e.g., subcutaneous abscess). Although lameness can be associated with such a swelling, clearly it is important to determine the cause of the abnormality because the one involving the joint may require the more immediate treatment.

13.3.1 Mechanisms of Swellings and Enlargements

The mechanism by which swelling or enlargement develops depends on the tissue involved (Box 13-6). Soft-tissue swelling often is produced by trauma, inflammation, infection, or neoplasia; it can consist of interstitial fluid (e.g., edema), fluid within an open space (e.g., synovial hernia), or a localized accumulation of cells or fibrous tissue. Localized edematous swelling commonly is caused by inflammation and/or obstruction of venous blood or lymph flow. Generalized edema is usually the result of increased hydrostatic pressure caused by circulatory failure or an altered capillary-tissue osmotic gradient stemming from hypoalbuminemia. Fluctuant swellings such as hematoma, synovial effusion, a purulent abscess, or a plasma-filled cyst contain free fluid. Granulation tissue, fibrous scar tissue, and tumor cells are the most common constituents of firm soft-tissue swellings. Rupture of supporting or confining structures (e.g., prepubic tendon rupture) can result in unusual forms of soft-tissue swelling caused by herniation of internal organs.

Many factors influence new bone formation. Trauma and infections initiate bony enlargement (e.g., callus) by disrupting the periosteum, producing inflammation and eventually ossification. The extent of periosteal new bone formation depends on the cause of the stimulus and the size of the affected area. Remodeled bone may also arise from nontraumatic events, usually associated with altered metabolism or neoplasia. Bony enlargements associated with the metaphysis and physis in young, growing animals are usually secondary to a combination of nutritional and traumatic factors. For example, dietary calcium, phosphorus, and vitamin D imbalance can lead to abnormal bone growth. A bony swelling develops gradually and may become noticeable only after it enlarges, interferes with normal function, or becomes a source of lameness.

13.3.2 Approach to Diagnosis of Swellings and Enlargements in Horses

1 History. A history should determine the number of horses involved, the duration of clinical signs, and the possibility that traumatic events or environmental factors are responsible for causing a swelling or enlargement. In addition, changes over time in the appearance and size of the swelling or enlargement can be informative.

2 Inspection and palpation. The location of the swelling and its proximity to anatomic structures often reveal the tissue involved and the probable cause of the condition. For example, swelling around a joint may indicate arthritis, periarthritis, or hygromas. Tendon swelling may indicate tendonitis or ruptured tendons. Swelling over ligaments may indicate rupture, subluxation, or inflammation around a ligament.

Muscle swelling results from abscessation or fascial tears. Subcutaneous swelling may indicate hematomas, edema from inflammation around a ligament, or cellulitis. Bony enlargements often can be localized to the shaft of a bone (e.g., periosteal callus) or the ends of a bone (e.g., metaphyseal flaring). Periarticular new bone may be readily apparent (e.g., ringbone) or may not be found even on deep palpation. New bone formation also can be found associated with the axial skeleton and head.

Palpation of a swelling can determine its consistency and association with anatomic structures. Osseous swelling indicates calcification, proliferation of bone, or fracture. Firm soft-tissue swelling indicates inflammation, abnormal proliferation of soft tissue (e.g., granulation, tumor), or herniation.

Warmth, redness, and pain associated with swelling indicate active inflammation. While new bone is forming, the swelling may be soft and sensitive to palpation. Cold and insensitivity to palpation suggest inadequate blood supply and possibly ischemia (e.g., gangrene).

Lameness caused by an injury or condition that results in a hard swelling or enlargement may be accentuated by performing a stress test, such as trotting the horse in hand after direct pressure on the swelling. Intraarticular anesthesia may substantially reduce a lameness caused by joint effusion associated with periarticular new bone.

3 Radiography, ultrasonography, and alternative imaging techniques. In addition to identifying definitively the nature of an osseous swelling or enlargement, radiography can gauge the severity and progression of the disease and help establish a therapeutic plan and prognosis. Ultrasound often can determine the position (e.g., depth, area) and volume of a soft-tissue swelling and the optimum site for aspiration or biopsy. Thermography may help to identify subtle heat production secondary to inflammation and increased blood flow, before onset of a swelling, allowing for early treatment. Nuclear scintigraphy may help to localize the cause of swellings and identify whether they are bony or soft tissue in origin (e.g., tarsal effusion secondary to a sustentaculum tali osteomyelitis). CAT scanning is useful for evaluating bony swellings, especially of the head when swellings of the mandible and maxilla may be related to infected teeth and the determination of which teeth are involved is necessary before surgical intervention. MRI may prove useful for accurate imaging of soft-tissue masses that cannot be accurately characterized with other diagnostic techniques.

4 Cytology, microbiology, and histology. A fine-needle aspiration, using aseptic techniques, should be performed to obtain samples for microbiologic culture (e.g., bacterial and fungal) of soft-tissue swellings. If the material is very viscous, a large-gauge needle may be required. Fluid collected for cytology should be placed in tubes containing ethylenediaminetetraacetic acid (EDTA) to prevent clotting before analysis. Tissue samples obtained by biopsy should be placed in 10% buffered formalin.

13.3.3 Approach to Diagnosis of Swellings and Enlargements in Ruminants

1 History. The history should indicate the duration of a swelling and whether it is congenital or acquired (Box 13-7). The rate of growth of a mass may be significant. The signalment of the ruminant sometimes gives a clue to the origin of the swelling; other ruminants in the herd should be examined for similar signs. Systemic manifestations (e.g., fever, anorexia, depression, and elevated pulse and respiratory rates) may indicate such things as blackleg, malignancies, and septic abscesses.

Traumatic stifle injury with fibrosis

Primary or secondary copper deficiency (molybdenosis) (e.g., physitis, spontaneous fractures)

2 Inspection and palpation. The origin of a swelling may be identified by the density and position of the mass on the ruminant. Masses over joints may represent hygromas or distention caused by synovial effusion. Skin masses may be edematous or parasitic nodules or neoplastic tumors. Muscle masses could be abscesses, herniations through torn fascia, or, in rare cases, neoplasia. Lymph nodes are most frequently enlarged because of abscessation, but neoplasia must be considered. Foot masses include interdigital fibromas and granulation tissue from chronic infections. Large osseous masses indicate calcification, bone proliferation, or a foreign body. When drainage is present in the center of a firm mass, a bone sequestrum is very likely. Firm soft-tissue masses may be granulomatous tissues, neoplasia, or a connective tissue scar.

3 Radiography and ultrasonography. (See comments for equine section.)

4 Cytology, microbiology, and histology. In some cases the density and location of a mass will be diagnostic and eliminate other possible diagnoses, but in many cases a microscopic examination of the tissue is necessary. Tissue can be obtained by needle aspiration, biopsy, or sometimes complete excision. Abscesses can simply be lanced, drained, and flushed. Unidentified tissue should be sectioned and stained for histopathologic examination and, in some cases, cultured.

13.4 PARESIS AND WEAKNESS

***Richard A. Lecouteur*,**

Paresis, may be defined as a deficit of voluntary movement. It may be monoparesis (paresis of a single limb), paraparesis (paresis of both pelvic limbs), tetraparesis (paresis of all four limbs), or hemiparesis (paresis of a thoracic and pelvic limb on the same side). Paresis results from disruption of the voluntary motor pathways that extend from the cerebral cortex, through the brainstem and spinal cord, to the motor unit (peripheral nerve, neuromuscular junctions, and muscle fibers). Complete loss of voluntary movement is referred to as *paralysis (plegia)*., Voluntary movements must be differentiated from reflex movements on the basis of neurologic examination findings and general observations.

Weakness, may be defined as impairment of strength and power. Most authors use the terms *paresis*, and *weakness*, synonymously; however, this may be confusing in some circumstances. For example, weakness may occur in the absence of paresis in some disorders of the nervous system, and weakness may result from many disease processes that do not primarily involve the nervous system (e.g., heart failure, respiratory insufficiency). The clinical signs of weakness may vary considerably and may include paresis, gait abnormalities, dysphagia, regurgitation, dyspnea, and dysphonia. Weakness may be present at rest or may occur after exercise. The distribution of involvement may be local, regional, or generalized. In addition, there may be gross deformities of muscle mass (e.g., atrophy, hypertrophy, skeletal deformities) associated with weakness.

This section focuses on paresis and weakness caused by conditions that affect the motor unit (Box 13-8). Diseases of other systems (e.g., respiratory and cardiovascular diseases or central nervous system disorders) that may result in paresis and weakness are discussed separately in other sections. 227 228

13.4.2

Mechanisms of Paresis and Weakness

Voluntary movement is initiated by the cerebral cortex. Muscular activity occurs subconsciously after activation of successively lower levels of the nervous system: basal nuclei, midbrain, pons and medulla, cerebellum, brainstem, spinal cord, and motor unit. The function of these lower levels is vital, and without their input voluntary movements become impossible.

Monoparesis (or monoplegia) is a common problem in horses and ruminants. It may be caused by dysfunction of the lower motor neuron or neuromuscular junction. Monoparesis is commonly caused by trauma to a nerve or plexus, although neoplasia (e.g., lymphoma, neurofibroma) and inflammation or infection (e.g., early stages of rabies) of peripheral nerves have been reported to cause monoparesis.

Bilateral pelvic limb paresis, ataxia, or paralysis may occur as a result of a neurologic disorder localized to the spinal cord caudal to the T2 spinal cord segment. Various congenital vertebral and spinal cord malformations may result in pelvic limb paresis. Equine protozoal myeloencephalitis and equine degenerative myeloencephalopathy may result in lameness, weakness, and ataxia that may progress to tetraparesis. Musculoskeletal disorders resulting only in bilateral pelvic limb weakness and paresis are unusual. Possible causes include trauma (e.g., postcalving or postfoaling paralyses caused by lumbosacral nerve root compression or contusion), vascular disorders (e.g., thrombosis), and early stages of an infectious disorder that may progress to tetraparesis.

The causes of tetraparesis are numerous and include progression of many of the disorders mentioned previously. Outbreaks of intoxication with *Clostridium botulinum*, occur sporadically in horses and ruminants; the condition results in a flaccid paralysis that starts with the pelvic limbs and progresses cranially. Depending on the amount of toxin involved, large numbers of animals may be affected. Polyneuropathies (congenital and acquired) and polymyopathies (congenital, metabolic, infectious, and immune-mediated) are causes of tetraparesis.

Muscle weakness may result either from a primary neuromuscular disease or disorders that affect muscle secondarily. In the latter category, problems of horses and ruminants that commonly result in weakness include poor diet, underfeeding, toxicity, and anorexia. Systemic diseases and disorders such as dehydration, low circulating blood volume, anemia, and metabolic abnormalities (e.g., acidosis or alkalosis) also may result in weakness. Disorders of bones (e.g., fractures) and joints (e.g., septic arthritis) affecting one limb also may affect the contralateral limb through overuse or misuse, and weakness of the contralateral limb may result.

Primary neuromuscular diseases usually are classified on the basis of the anatomic component of the motor unit that is involved. Such diseases broadly are subdivided into neuropathies (disorders of the neuron, its cell body, axon, and/or Schwann cells [myelin]); junctionopathies (disorders of the neuromuscular junction); myopathies (disorders of muscle fibers); and neuromyopathies (disorders of both the neurons and the muscle fibers).

Dysfunction of the motor unit results in lower motor neuron signs, seen clinically as muscle weakness. The expression of this weakness may vary considerably, and the distribution of involvement may be local, regional, or generalized. Atrophy, hypertrophy, and skeletal deformities may accompany the muscle weakness. Any patient with some form of clinical weakness should be viewed as potentially having a motor unit disorder. That the patient is “weak merely because it is sick” should not be readily assumed without meticulous evaluation of the motor unit.

13.4.3 Approach to Diagnosis of Paresis and Weakness in Horses

Establishing a diagnosis requires an informed and coordinated approach to defining a problem list through associations and direct observations (i.e., a diagnostic plan) (Box 13-9).

1 Signalment. Breed, age, sex, and use of the horse.

2 History. Feeding program, vaccination and deworming schedules, course of complaint, response to treatment, and possibility of exposure to toxins or trauma.

3 Physical examination. Presence and distribution of abnormal findings on physical and neurologic examinations should be recorded. Normal functions must be known before abnormal functions may be recognized. Abnormal functions must be recognized because neurologic diseases are manifested clinically almost entirely by dysfunction. It is uncommon for the clinical signs to include readily detectable anatomic changes. Therefore a clinician must rely on clinical signs of abnormal function to identify the location of the neurologic dysfunction.

   The first step in locating a neurologic lesion is to determine the level of the abnormality along the longitudinal plane of the neuraxis (i.e., brain, spinal cord, or motor unit). The second step is to further localize the lesion within an anatomic region (e.g., motor unit should be further localized to peripheral nerve, neuromuscular junction, or muscle). The third step is to determine the location of the lesion in the transverse plane at the appropriate longitudinal level (e.g., left or right side).

4 Minimum database. Complete blood count, serum biochemistry panel (including electrolyte determinations), fecal analysis, and urinalysis. Measurement of muscle-specific serum enzymes, such as creatine kinase (CK), as well as aspartate aminotransferase (AST) and lactic dehydrogenase (LDH) may be helpful in identifying neuromuscular disorders in which myonecrosis is a principal pathologic feature. Elevated serum enzyme activities may help to differentiate myopathies from other neuromuscular disorders. Immunologic procedures for the detection of myoglobin that are becoming available may provide a sensitive means of detecting myolysis in the future.

5 Specific diagnostic tests

   a Electrodiagnostic testing. Electromyography (EMG) involves the detection and characterization of electrical activity (potentials) recorded from a patient's muscles. A systematic study of individual muscles permits an accurate determination of the distribution of muscles affected by a pathologic process.

   b Nerve and muscle biopsy examination. This procedure evaluates the morphology of portions of the motor unit and may differentiate neuropathies, junctionopathies, and myopathies. In some instances, results of muscle biopsy analysis may provide a definitive diagnosis (e.g., polysaccharide storage myopathy of horses).

13.4.4 Approach to Diagnosis of Paresis and Weakness in Ruminants

The approach to the diagnosis of disorders causing paresis and weakness in ruminants is essentially the same as that for horses (Box 13-10). Differences may be encountered as a result of the intended use of ruminants. Most ruminants live in a herd setting, and the level of human supervision and care of the herd will vary. In some cases animals will be monitored daily for signs of abnormal behavior, whereas in other cases animals may not be observed for varying periods of time. Infectious diseases, disorders arising from nutritional problems, parasites, or toxicity may progress to affect several individuals before a problem is noticed. Signalment, history, and a physical and neurologic examination are essential to determine first if the paresis and weakness are neurologic in origin and second to make a neuroanatomic diagnosis. These findings should be combined with a knowledge of diseases and disorders that produce this clinical picture in order to arrive at a diagnosis.

13.5 MUSCLE SPASMS AND MYOCLONUS

***Richard A. LEcouteur*,**

Muscle spasms are sudden, transient, and involuntary contractions of a single muscle or group of muscles, attended by pain and loss of function. Often all the muscles affected by a spasm are supplied by a single nerve. A painful, tonic, spasmodic muscular contraction is often referred to as a *cramp*.,

Myoclonus, may be defined as a disturbance of neuromuscular activity characterized by abrupt, brief, rapid, jerky, arrhythmic, asynergic, involuntary contractions involving portions of muscles, entire muscles, or groups of muscles, regardless of their functional association. The movements may be single or repetitive (10 to 50 per minute) and are similar to those that follow stimulation of a muscle. Myoclonus is seen primarily in muscles of the limbs, where involvement is often diffuse or widespread. Myoclonus also may be present in facial or masticatory muscles and muscles of the tongue, larynx, and pharynx. Myoclonus usually disappears during sleep.

This section describes muscle spasm and myoclonus as specific clinical signs associated with dysfunction of the musculoskeletal system.

13.5.1 Mechanisms of Muscle Spasms and Myoclonus

Spasms usually are of reflex origin and may result from irritation or stimulation at any level of the nervous system from the cerebral cortex to the muscle fibers. In most cases, however, spasms are caused by peripheral irritation affecting either muscles or nerves. Pain may cause either tonic or clonic spasms of muscles, especially should the painful stimulus be focal or discrete. Mechanical irritation may cause a localized spasm. There may be prolonged and characteristic muscle spasm associated with the hyperirritability of nerves and muscles in tetany or tetanus. Spasms may follow injury or irritation of peripheral nerves, particularly during the process of regeneration. Spasms may also result from irritation or diseases affecting cortical centers in the brain, motor nuclei in the brainstem, or descending motor pathways in the spinal cord.

There has been much discussion regarding the pathologic process underlying myoclonic movements. Whereas originally it was thought that the neural discharge that excites the muscular contraction of myoclonus was confined to the motor unit, it is now known that myoclonus also may result from dysfunction of the brain (cerebral cortex, brainstem, basal nuclei, thalamus, etc.), spinal cord, peripheral nerve, neuromuscular junction, or the muscle itself, alone or in combination. A variety of processes evidently lead to hyperexcitability of the cerebral cortex, subcortical structures, or even the lower motor neurons alone. Myoclonic movements or muscle spasms may occur in a variety of conditions. They have been observed in association with encephalitis, meningitis, toxic and postanoxic states, metabolic disorders, degenerative diseases, and vascular and neoplastic conditions. Myoclonus has also been reported in association with lesions of peripheral nerves, nerve roots, and spinal cord.

Specifically, disturbances in plasma electrolyte concentrations, certain drugs, toxins, and poisons may elicit involuntary muscle activity. In general, the mechanism that is common to all causes of spasm or myoclonus involves an inappropriate stimulation of a nerve or muscle cell, causing the cell to fire a series of action potentials, resulting in muscle contraction. For example, toxins may act directly on the muscle cell membrane to stimulate the release of calcium into the cell from the sarcoplasmic reticulum, thereby causing involuntary muscle contraction. Alternatively, some toxins may cause efferent neurons to release neurotransmitter across the neuromuscular junctions, thereby stimulating receptors on the muscle cell membrane.

13.5.2

Approach to Diagnosis of Muscle Spasms and Myoclonus in Horses

A broad spectrum of diseases may be associated with muscle spasms or myoclonus in horses (Box 13-11). A thorough investigation is needed to achieve an accurate diagnosis.

1 History. A comprehensive history including evaluation of the environment and stablemates, description of any traumatic episodes, and any potential drug or toxin exposure.

2 Physical examination. Complete lameness and neurologic examinations should be done as extensions of a thorough physical examination.

3 Minimum database. Complete blood count, serum biochemistry panel (including muscle enzyme determinations), and cerebrospinal fluid analysis should be performed. In the case of muscle spasm and myoclonus, elevation in muscle enzymes may indicate secondary muscle damage rather than a primary muscle disease. A tetany panel, including serum calcium, phosphorus, and magnesium determinations, may be completed. Hypocalcemia may be a cause of muscle spasms in lactating horses, exhausted endurance horses, or horses transported long distances.

4 Specific diagnostic tests.

a Electrodiagnostic testing. A systematic study of individual muscles using EMG permits an accurate determination of the distribution of muscles affected by a pathologic process.

b Nerve and muscle biopsy examination. This procedure evaluates the morphology of portions of the motor unit and may differentiate neuropathies, junctionopathies, and myopathies. In some instances results of muscle biopsy analysis may provide a definitive diagnosis (e.g., phosphorylase deficiency of Charolais cattle).

13.5.3 Approach to Diagnosis of Muscle Spasms and Myoclonus in Ruminants

The approach to diagnosis of muscle spasms and myoclonus in ruminants is essentially the same as that described for horses (Box 13-12). In ruminants a tetany panel (consisting of serum calcium, phosphorus, and magnesium determinations) should be completed in any animal exhibiting these signs. In lactating cattle on grass pasture, and in sheep transported long distances, hypomagnesemia and hypocalcemia, respectively, are highly suspected initially. Several infectious (e.g., rabies, pseudorabies), toxic, and inherited causes of muscle spasms and myoclonus should be suspected in ruminants. In postparturient animals and animals with wounds or bites, or animals recently castrated or tail docked, tetanus should be considered as a possible cause of muscle spasms and myoclonus.

14 Chapter 14 Collapse and Sudden Death

Stan W. Casteel

James R. Turk

The ruminant or horse that collapses and dies within 24 hours while being observed or is found dead with no premonitory signs of illness is often a diagnostic challenge. In these situations clients often are distressed and frequently pressure the veterinarian to declare an immediate diagnosis. Sudden death in the absence of observed clinical illness is usually the most perplexing. Obligation to clients necessitates a systematic approach to derive a specific causative diagnosis, to determine the source and extent of the problem, and to recommend corrective measures. These goals are best accomplished by delineating the characteristics of normal animals within the herd and analyzing the distribution of the disease with respect to time, place, and a variety of exposure factors and environmental influences. These factors are then correlated with necropsy results and additional diagnostic testing.

14.1 COLLAPSE VS. SUDDEN DEATH

Collapse is easily identified as a state of extreme prostration and depression. However, sudden death has a somewhat tenuous meaning, lending itself to subjective impression. The timing parameter used to define sudden death ranges from 1 to 24 hours from the onset of the fatal episode. Some veterinarians restrict the definition to a narrower time span. The 12- to 24-hour interval is sometimes selected to coincide with the frequency of owner observation of the livestock. For our purposes sudden death means clinically unexplained, rapid death (12 to 24 hours) occurring during normal activity in apparently healthy animals. Generally a condition of this nature is associated with fatal dysfunction of the cardiovascular, nervous, respiratory, or gastrointestinal (GI) system. In addition, perturbations in general cellular metabolism (cyanide or hydrogen sulfide) may result in peracute death.

14.1.1 Approach to Diagnosis of Sudden Death

The causes of sudden death are investigated in much the same way as for any disease. The accompanying tables of differential diagnoses include infectious, metabolic, nutritional, physical, cardiovascular, toxic, and miscellaneous causes of sudden death. Diagnostic laboratories provide an array of tests and analytic procedures based on the needs of veterinarians in their service areas. Use of these facilities to support a definitive diagnosis is essential in sudden death cases. Diagnosis is rarely based on a single item of evidence and usually requires input from multiple testing procedures. Unless the cause of death is apparent, some important considerations required for effective use of a diagnostic laboratory include the following:

1 A detailed history, which consists of the herd incidence, management changes, past medical problems, vaccination records, new additions to the herd, a complete description of the environment, and a recognition of the frequency of animal observation. Owners and managers may not be candid for fear of being considered negligent. Inconsistencies among involved parties should be carefully evaluated. Recent changes in management practices should be scrutinized, including feeding habits and whether there have been any illnesses in commingled animals. Animals trailed or transported for long distances or introduced onto unfamiliar ranges often are poisoned by plant species normally avoided by indigenous livestock. The likelihood of foul play should be considered without creating undue alarm. Assigning blame should be left to the discretion of owners. Consideration of disgruntled former employees and equine insurance claims are particularly critical situations that may have legal implications. The precise cause of death is crucial for insured livestock (mostly horses) because of exclusion clauses in many insurance policies. Heavily

insured horses should be subjected to a detailed, documented, and witnessed diagnostic evaluation. Toxicologic testing is especially critical in these cases. Evaluation of the environment before the animal is moved is necessary to eliminate questionable procedures in insurance claim cases. Evidence of struggling in the immediate area indicates a more protracted illness in contrast to collapse and death without a struggle. Suspicions should be aroused when evidence suggests the animal may have been dragged or carried to the current location.

2 The appropriate specimen is required by the diagnostic laboratory to perform the requested examination. Many cases of sudden death are attributed to central nervous system dysfunction; therefore it is necessary to remove the brain. Busy practitioners frequently do not take the time to remove this organ. There is a higher-than-normal probability of a poison being involved in sudden death cases, especially in equine insurance claims. For toxicologic examination, toxicants remaining in the GI tract must be considered, together with those in the major excretory organs, the liver and kidneys. 232 233

3 The correct amount and preservation of the sample depends on the specific test. Medicolegal cases demand that stringent photographic and written documentation, witnessing, and chain-of-custody protocol be followed during necropsy and sample collection. The amount of the sample is particularly important for chemical analysis. Sending insufficient quantities of sample may preclude multiple testing procedures. In general, 100 to 200 g of tissue or ingesta, 50 mL of urine, all fluid from both eyes, and 5 to 10 mL of blood or serum suffice for most analytic procedures. A midsagittal cut through the brain is performed to allow freezing of one half for chemical analysis and formalin preservation of the other. When poisoning is suspected, samples from possible sources such as feed, water, baits, poisonous plants, and suspect materials should be submitted. Usually 1 kg of each is adequate. Samples submitted for chemical analysis should be frozen in individual containers and labeled with date, location, and identity of the specimen. Specimens for bacteriology and virology are to be packaged separately and chilled. Dry ice should be avoided because gaseous carbon dioxide may kill some infectious agents. Tissues for histopathologic examination require fixing in 10% formalin with tissue slices 4 to 5 mm thick. Suspected poisonous plants are properly preserved by placing them in a plastic bag with wet paper towels or by drying them between sheets of paper.

14.2 CAUSES OF COLLAPSE AND SUDDEN DEATH

14.2.1 Infectious Causes of Sudden Death in Horses (Box 14-1)

Foal actinobacillosis is an acute fulminant septicemia caused by *Actinobacillus equuli*, a gram-negative bacterium found in the upper respiratory tract, feces, and genital tract of normal adult horses. Predisposing factors to foal septicemia with any agent include prematurity, failure of passive transfer, dam malnourishment during gestation, and environmental stress. A characteristic histologic finding is multiple bacterial emboli in renal glomerular capillaries without inflammatory infiltrate in neonatal foals. Acute anthrax may be rapidly fatal to horses after a period of excitement, depression, convulsions, and coma. Isolating the causative agent from blood confirms the diagnosis. Babesiosis is an erythrocytic parasite that may cause death within 24 hours. Identification of the organism in blood smears or complement fixation testing for parasite antibodies confirms the diagnosis.

14.2.1.1

Salmonellosis*

Tyzzer's disease

* Likely to involve several animals.

Acute clostridial disease involving *Clostridium septicum, Clostridium chauvoei, Clostridium novyi*, and *Clostridium perfringens*, has been associated with intramuscular injections of various parenterals such as ivermectin, vitamin B complex, prostaglandin, antihistamines, and flunixin meglumine when asepsis has been ignored. Clostridial myopathies also are associated with deep stab or puncture wounds. Botulism in foals (shaker foal syndrome) is caused by *Clostridium botulinum*, (usually type B). Toxin may sometimes be demonstrated in feed and gut contents. The organism may be cultured from tissues or gut contents in toxico-infectious cases.

Clostridium sordellii, should be suspected in cases of foals having a history of colic, bloody diarrhea, and death within a few hours.[1] *C. perfringens*, type C may induce a hemorrhagic enterotoxemia and death in foals as young as 4 days.[2] Severe intestinal lesions are caused by the beta-toxin produced by this species. Organisms may be demonstrated in smears of intestinal contents. *C. perfringens*, type D also induces sudden death in the most aggressive foals in group-feeding situations. Similar enterotoxemia also has been associated with toxin-producing *Clostridium difficile*,[3] and *Bacteroides fragilis*.,[4]

Equine monocytic ehrlichiosis (Potomac fever), caused by *Ehrlichia risticii*, is a severe colitis with diarrhea and dehydration, followed by ileus, endotoxemia, and death in adult horses. Diagnosis is based on clinical findings and antibody and antigen detection using immunofluorescent antibody (IFA) and enzyme-linked immunosorbent assay (ELISA) methods, respectively. Guttural pouch mycosis often results in nonfatal intermittent unilateral epistaxis. Occasionally a single episode of severe epistaxis from rupture of an aneurysm in the internal carotid artery may result in sudden death. Necropsy reveals blood in the nasal passages and guttural pouch with a diphtheritic plaque in the dorsocaudal aspect of the medial compartment. Salmonellosis is responsible for many cases of acute enterocolitis, especially when several animals are involved. The peracute syndrome may resemble colitis-X in mature horses with a course of 6 to 12 hours. Horses may die before diarrhea develops. Postmortem diagnosis is based on isolation of *Salmonella*, species from bowel contents, bowel wall, and/or associated lymph nodes. Tyzzer's disease is a rapidly developing fatal hepatitis of foals. The incidence is sporadic, and, because of the peracute development, clinical signs may not be observed before death. Diagnosis is based on histologic demonstration of the bacilli in bundles within hepatocytes surrounding necrotic areas.

14.2.2 Infectious and Parasitic Causes of Sudden Death in Ruminants

Infectious causes of sudden death range from acute septicemias and toxemias to rupture and release of abscess contents into the systemic circulation (Box 14-2). A liver abscess rupturing into the caudal vena cava; endocarditis, especially of the right atrioventricular valve, with subsequent pulmonary thromboembolism; and the rupture of a pituitary abscess are occasional causes of sudden death in individual animals. Acute anthrax and the clostridial infections, as well as ingestion of their preformed toxins, are more common causes of sudden death in ruminants. Anaplasmosis may cause sudden death in mature cattle under stress, without apparent icterus. 233
In these cases anthrax may be mistaken for anaplasmosis because of the gross enlargement of the spleen. 234
Anaplasma, organisms may be demonstrated in blood smears, whereas newer diagnostic methods involve indirect fluorescent antibody and DNA probes. Of all domestic animals, cattle are the most susceptible to clostridial infections in which tissue invasion is present (blackleg). Because of this, vaccination status is important to ascertain. In addition, a fluorescent antibody test and isolation of the bacterium confirm the diagnosis. *C. perfringens*, of various types is responsible for heavy losses caused by enterotoxemia in calves, lambs, kids, and feedlot cattle in apparent good health and on full feed. *C. perfringens*, type D has been associated with focal symmetric encephalomalacia in lambs.[5] *Coliform*, mastitis may result in peracute systemic disease and rapid death if not treated early. Diagnosis is based on culture of the organism from the affected gland. *Leptospira*, may cause an acute septicemia with hemolytic anemia and rapid death in young ruminants. Demonstration of leptospires in fresh urine or by immunohistochemical staining of tissues may assist in making the diagnosis. The course of listeriosis in sheep and goats is rapid, and death may occur in 4 to 48 hours after the appearance of clinical signs.[6] Bacteriologic culture (isolation) or immunohistochemical staining of the organism in tissues is diagnostic. Acute fascioliasis *(Fasciola hepatica)*, occurs seasonally in sheep and may cause sudden death within 6 weeks of initial infection. Anaerobic conditions induced by flukes in hepatic parenchyma predispose ruminants to the highly fatal clostridial hepatopathies such as *Clostridium hemolyticum*, infection. Evidence of fluke infection is grossly visible. Peracute malignant catarrhal fever (MCF) is a sporadic cause of sudden death in cattle that is usually associated with contacting ovine carriers, but most animals with MCF have

diarrhea, keratitis, and other obvious clinical signs for days before death occurs. A septicemic form of mycoplasmosis has induced rapid death in kids.[7] Isolation of the causative organism is diagnostic. Sudden death is the usual manifestation of septicemic pasteurellosis in lambs. Pseudorabies is a consideration in sudden death cases of ruminants having contact with infected swineherds in the Midwestern United States. Brain for microscopic examination and virus isolation should be submitted to confirm the diagnosis. Acute septicemic salmonellosis mainly affects young ruminants and may result in death within 24 hours. Acute septic metritis usually occurs secondary to complications of parturition. Endotoxic shock and rapid death may occur in severe cases. Thromboembolic meningoencephalomyelitis caused by *Haemophilus somnus*, is a peracute septicemic disease of young calves. Many cattle die without showing clinical signs. It may be associated with prior respiratory problems in the herd or feedlot. Typical lesions or isolation of the causative organism is diagnostic. Adult lymphosarcoma associated with bovine leukemia virus can be a cause of sudden cardiac death when neoplastic cells infiltrate the cardiac conduction system.

14.2.3 Metabolic and Nutritional Causes of Sudden Death in Horses

Hypocalcemia in horses is most common in lactating mares, but it also occurs after transit. Animals may develop tetany, synchronous diaphragmatic flutter (thumps), muscle tremors, and sweating. Low serum calcium is diagnostic. White muscle disease (nutritional myodegeneration) is associated with selenium and vitamin E deficiency. Sudden death in adult horses after severe exercise is attributed to degenerative lesions in cardiac and skeletal musculature. Death in foals may occur within hours from pulmonary edema and heart failure. Diagnosis is based on measuring whole blood and/or liver selenium and vitamin E concentrations.

14.2.4 Metabolic and Nutritional Causes of Sudden Death in Ruminants

Metabolic and nutritional diseases often are not considered in cases of sudden death. The primary lesion in a disorder of cattle known as “falling disease” is progressive fibrosis of the myocardium. Sudden deaths characteristic of the disease are attributed to exercise-induced heart failure.[8] Rapid development of hypocalcemia

usually is associated with the onset of lactation in cattle, with stressful circumstances in older lactating ewes, or with transport associated with fasting and weather stress. Hypomagnesemia also may develop under similar conditions, especially in ewes and cows in heavy lactation and on lush grass pastures. Polioencephalomalacia occurs most commonly in animals raised under intensive production techniques and can sometimes be traced to excessive sulfates in the diet and/or water. The clinical course tends to be most rapid in sheep. Severe cases of ruminal lactic acidosis, especially in animals unaccustomed to high levels of soluble carbohydrate in the diet, may induce death within 24 hours. Nutritional myodegeneration of the heart is a frequent cause of sudden death in young ruminants born to dams fed selenium-deficient diets during gestation. Diagnosis is based on histopathology and measurement of liver selenium concentration. Some cases of sudden death associated with myocardial necrosis are idiopathic.[9]

234

235

14.2.5 Cardiovascular Causes of Sudden Death in Horses

Diagnosis of sudden death caused by cardiovascular failure depends on a careful and methodic technique (Box 14-3). Usually a single animal is affected. Necropsy is necessary to identify the location and characteristics of the lesion, and further analysis may be necessary to establish the exact cause of death. Aortic ring (root) rupture in stallions usually is seen early in the breeding season, occurring immediately after servicing a mare. Rupture of the aorta may occur just distal to the aortic valve, resulting in cardiac tamponade and rapid death. Acute central nervous system embolism results from detached thrombi originating from endocarditic lesions or accidental intracarotid injection. Cerebral hematoma also can result from intracarotid injection. Endocarditis, especially of the aortic valve, may result in coronary thromboembolism and myocardial infarction. Coronary occlusion as a result of damage induced by *Strongylus vulgaris*, larvae can be diagnosed by the presence of the larvae in the coronary thrombus. Massive abdominal or thoracic hemorrhage is found at necropsy, and the cause may be difficult to ascertain.[10] Racehorses mostly die from severe hemorrhage in the thorax. Myocarditis in horses up to 4 years of age resulting from recent respiratory infection may be diagnosed with histopathologic examination. Pericardial rupture and the associated heart damage is a result of violent trauma. Splenic rupture and fatal hemorrhage rarely occur because of the protection afforded by the thoracic wall. Massive thrombi of verminous origin have been observed in young horses that die suddenly while exercising. Uterine arterial rupture involving ovarian, uteroovarian, uterine, or external iliac arteries is observed in older mares, with death ensuing in 30 minutes to 20 hours' postpartum.

14.2.6 Physical Causes of Sudden Death in Horses

Fatal air embolism can result from any open vein above the heart. Open needles or catheters and severe head wounds involving teeth and sinuses have resulted in sudden death from air emboli. Air is aspirated into the vein by the Venturi effect from blood surging past a portal and creating the necessary negative pressure to aspirate air into the vein. Between 700 and 6000 mL of air may produce a fatal air embolus in the right cardiac ventricle, where it obstructs the pulmonary artery. Cecal or colonic rupture in parturient mares results in sudden death within 8 hours.[11]

14.2.7 Physical Causes of Sudden Death in Ruminants

Physical causes of sudden death often display gross evidence indicative of the diagnosis. Abomasal bloat occurs in calves and lambs drinking excessive quantities of warm milk replacer at infrequent intervals. Abomasal ulcers occasionally may perforate and cause rapid death in calves or adult cattle. Ruminal bloat is one of the more common physical causes of sudden death in intensively raised ruminants. When differentiating postmortem from

antemortem bloat, note that bloat is the primary cause of death when there is congestion and hemorrhage in the anterior parts of the carcass and edema in the scrotal and ventral perineal areas. Bloat and hypersalivation are the most consistent clinical signs seen in cases of choke. Attempts to swallow firm fruits, tubers, or green ears of corn may occlude the esophagus and result in rapid ruminal tympany and death.

Sudden death is a major concern in feedlots because most such deaths occur in cattle near market weight. GI disturbances are seen with a high frequency in cattle in the late stages of the feeding program. Sudden death is the result of interactions among factors such as rumen acidosis, bloat, and endotoxemia.

Box 14-3 Cardiovascular Causes of Collapse and Sudden Death in Horses

Aortic ring (root) rupture

Central nervous system embolism

Coronary occlusion

Endocarditis

Massive abdominal or thoracic hemorrhage

Myocarditis

Pericardial rupture

Splenic rupture

Thrombi of verminous origin

Uterine arterial rupture

Exposure to high-voltage currents in the form of lightning or electrical transmission wires may cause instantaneous death. The diagnosis of lightning strike is based on a history of an electrical storm, linear singe marks, food in the mouth, several animals dead in the same vicinity, and evidence of lightning damage in the immediate environment. Gunshot wounds may be deliberate or accidental, but in any case involving sudden death the head or heart is the usual target. Bullets may pass through or lodge in obscure locations, making retrieval difficult. Radiography can assist in locating a bullet. Heatstroke is a sporadic condition characterized by hyperthermia and collapse. High humidity, dehydration, obesity, and poor heat tolerance associated with young or old age are all factors that predispose animals to overheating. Summer slump induced by consumption of endophyte-infected fescue potentiates the heat intolerance. Internal bleeding may cause sudden death when a uterine artery is ruptured during parturition. This is readily apparent on necropsy. Tracheal edema, or “honker” syndrome, of feeder cattle is seen sporadically in feedlot cattle of the southern plains during hot weather. The

pathoanatomic basis of this syndrome is extensive edema of the mucosa and submucosa of the lower trachea, with attendant dyspnea and obstructive asphyxiation. Increased respiratory movements stimulated by hot weather or exercise trigger the clinical illness, especially in heavy cattle during the latter part of the feeding period.[12] Traumatic reticuloperitonitis or reticulopericarditis is associated with lack of oral discrimination in cattle. Sudden death occurs because of acute hemorrhage or dysrhythmia when the heart is punctured.

14.2.8

Toxic Causes of Sudden Death in Horses

Toxic causes of sudden death are frequently related to management practices. An increase in specific disease syndromes or sudden death in a population of livestock with common potential exposures suggests involvement of a toxicant. Investigation of the premises and a familiarity with poisonous plants and pesticides used in the practice area should help narrow the list of possible causative agents (Box 14-4).

Horses ingesting a lethal dose of the avicide 4-aminopyridine have died within 2 hours of the onset of clinical signs. Diagnosis is based on chemical analysis of stomach contents. Fatal doses of arsenic-containing pesticides may induce cardiovascular collapse and death in horses within hours of ingestion. The presence of edema and fluid in the GI tract suggests the diagnosis, and chemical analysis of GI tract contents, liver, or kidney confirms it. Black flies swarm where swiftly flowing water provides the aeration necessary for the development of larvae. 235
Massive attacks of these blood-sucking insects can rapidly kill livestock because a toxin present in the saliva of 236
the flies increases capillary permeability.[13] Cantharidin poisoning can occur after ingestion of 4 to 5 g of blister beetles. Lesions suggestive of cantharidin toxicosis include blistering and ulceration of mucous membranes of the GI and urinary tracts and myocardial degeneration and necrosis. Sustained hypocalcemia and hypomagnesemia are features of the clinical pathology consistent with blister beetle poisoning. Identification of blister beetles in the hay and chemical analysis of urine and GI contents are suitable for diagnostic confirmation. In the past, ferrous fumarate, present in digestive inoculate and administered to foals immediately after birth, resulted in death in some cases in 12 to 96 hours. This illustrates the acute toxicity of iron to young animals in particular. Lesions induced were those of gross liver damage. *Fusarium moniliforme*,–contaminated corn causes rapid death in horses after the sudden onset of bizarre neurologic deficits and behavioral effects. The lesion of this mycotoxin-induced leukoencephalomalacia is liquefactive necrosis in the subcortical white matter.

High intravenous doses of insulin[14] and potassium[15] induce sudden death without significant lesions. Chemical detection is often overlooked and very difficult to perform and interpret in cases of deliberate poisoning. Immediate analysis of blood and circumstantial evidence of needle punctures in the jugular furrow are of diagnostic value. Monensin is quite toxic to horses, and fatal poisoning can occur within 12 hours of ingestion of poultry feed containing 100 g/ton or cattle premixes containing 300 g/ton. Lesions related to heart failure are

seen on postmortem examination. Tissues collected for microscopic examination should include heart and diaphragm. Chemical analysis of feed samples and stomach contents will confirm exposure. Toxic gases such as nitrogen dioxide, hydrogen sulfide, and carbon monoxide may be responsible for sudden death in horses housed in poorly ventilated buildings with associated gas sources nearby. Organophosphate and carbamate insecticides may induce acute intoxication and death within hours. Diagnosis is based on a history of exposure, determination of acetylcholinesterase activity in the caudate nucleus of the brain, and chemical detection of specific compounds in gut contents.

Circumstances surrounding toxic plant ingestion and diagnosis of intoxication are described in the ruminant section of this chapter. Ingestion of wilted *Acer rubrum*, (red maple) leaves may induce massive methemoglobinemia, causing marked tissue anoxia and death.[16] Red maple poisoning usually occurs during the late summer and early fall when trees are in full leaf. Ready access to wilted leaves follows windstorms. *Ricinus communis*, or castor bean, is also unique to this section. Seeds of this plant contain a phytotoxin called ricin, which causes severe enteritis and rapid death in horses. About 150 beans (50 g) are sufficient to kill a 450-kg horse. Diagnosis can be verified by finding a toxic amount of ingested seeds in the gut contents.

14.2.9 Toxic Causes of Sudden Death in Ruminants

Intoxication of livestock is frequently suggested as a simple explanation for very complex situations involving sudden death. Suspicions are warranted when a large number of animals die suddenly within a short time. Toxicants should be considered when the appearance of a disease or sudden death is temporally associated with a change in the environment (Box 14-5). An accurate diagnosis in many of these cases requires qualitative and quantitative analyses for suspect poisons. Selecting toxicants for which to analyze requires reasoned judgment supported by an extensive investigation of the environment and postmortem findings.

The avicide 4-aminopyridine usually is formulated with corn, making it a palatable poison for nontarget herbivorous livestock. Diagnosis is confirmed by chemical analysis of rumen contents or urine. Anticoagulant intoxication may induce sudden death when hemorrhage occurs in the cranial vault, abdominal cavity, pericardial sac, mediastinum, or thorax. The antemortem or postmortem sample for chemical analysis is whole blood or liver. Failure to detect an anticoagulant is not unusual because of the time lag between consumption and presence of the clotting defects, as well as the metabolism of the compound. Arsenic derivatives are a significant hazard to ruminants, especially in areas where such chemicals are widely used as cotton desiccants. Postmortem findings are consistent with microvascular injury to the GI tract. Diagnosis is confirmed by chemical analysis of rumen contents, liver, or kidney. In rare cases large doses of botulinum toxin may cause sudden death in ruminants. Sources of the toxin include the bones of dead animals eaten by osteophagic livestock, poultry carcasses in manure fed to cattle, stagnant pond water, animal tissues in silage or baled hay, and improperly ensiled silage or haylage.

Acetylcholinesterase-inhibiting agents such as the carbamate and organophosphate pesticides can kill livestock within hours. Agricultural practices result in the use of these pesticides in close proximity to livestock. This situation may lead to disaster. Acetylcholinesterase activity in the caudate nucleus of the brain is readily determined and interpreted, and specific compounds may be identified in rumen contents. Toxic gases such as carbon monoxide, hydrogen sulfide, and nitrogen dioxide become important differentials for sudden death in ruminants housed in poorly ventilated buildings, particularly over waste pits. Chlorinated hydrocarbon pesticides do not enjoy the widespread use they once did; however, old containers remain in obscure locations on many farms. When acute intoxication with these compounds is suspected, samples for analysis should include liver, brain, and rumen contents. In subacute cases fat and milk are appropriate samples. Copper toxicosis is a frequent cause of sudden death in sheep and has been reported in cattle fed chicken litter.[17] Cattle feeds normally contain

twice as much copper as sheep feeds and may cause copper toxicosis in sheep. Copper from treated fence posts also may poison sheep that either chew the posts or ingest contaminated forage in the vicinity. Samples required for chemical confirmation consist of whole blood or serum and liver. Close proximity of livestock to petroleum exploration and production activities in the major oil-producing states results in a variety of clinical problems, including sudden death.[18] Consumption of the more volatile petroleum constituents may induce rapid bloating and coating of the respiratory membrane when these substances are aspirated into the lungs. Gossypol toxicosis reportedly causes death without premonitory signs in calves (occasionally cows) and lambs fed cottonseed products containing this toxic pigment.[19,20] Poisoning appears abruptly after livestock have been fed the gossypol-containing ration for a period of weeks to months. Sudden death is attributed to heart failure. Postmortem examination reveals edema, centrilobular hepatic necrosis, and an enlarged heart. Ionophores may induce sudden death in species exposed to large overdoses, but delayed death is the usual course. Conditions conducive to lethal overdose include insufficient mixing or top dressing with monensin- or lasalocid-supplemented mineral. Degenerative-to-necrotic lesions in the heart are compatible with a diagnosis of ionophore poisoning.

* Likely to involve several animals.

Acute lead intoxication is another differential from the list of possibilities in sudden death cases. Lead poisoning is the most common toxicosis in cattle. Blood, liver, and kidneys are suitable specimens for lead analysis. Metaldehyde is an uncommon poison for ruminants; however, intoxication in cattle has occurred in low wetland areas where the chemical is used as a molluscicide. The palatability of metaldehyde baits promotes ingestion. Ammoniation of high-quality forage such as forage sorghum and Sudan grass, cereal grain, brome, and fescue hays is responsible for bovine bonkers syndrome, reportedly caused by the formation of 4-methyl-imidazole.[21] This sporadic intoxication causes central nervous system derangement and rapid death in cows and nursing calves. Ruminants may be poisoned by nicotine sulfate from ingestion of solution, treated foliage, and food or water from contaminated containers. The onset and progression of the syndrome are rapid, and death may occur within hours. Detection of nicotine in urine is easily performed by most toxicology laboratories. Iatrogenic selenium toxicosis and death in young ruminants can result from parenteral administration of excess doses. Rapid onset of violent tetanic seizures ending in death characterizes strychnine toxicosis. Samples suitable for chemical analysis include rumen contents, liver, and urine.

Urea toxicosis is a frequent cause of sudden death in feedlot livestock. In one particular case, 48 feedlot steers died within 2 days of delivery of a new lot of feed supplemented with urea.[22] Unusually high rumen pH, excess ammonia in serum, rumen contents, and eyeball fluid support the diagnosis. Water deprivation, with attendant sodium ion intoxication, is a known cause of sudden death in ruminants.[23] Some cases occur in hot weather, but frozen water supplies in cold weather can be equally as devastating.

Poisonous plant problems frequently present a unique set of circumstances associated with their ingestion. Overgrazing of pastures is probably the most significant factor affecting the ingestion of toxic plants. Other situations conducive to poisonous plant ingestion include lack of suitable forage in periods of drought and the incorporation of toxic forbs in hay or greenchop. Plants normally avoided because of poor palatability may become acceptable when frosted or sprayed with herbicide. Toxic plants also may be the first green plant available early in the spring, when livestock are hungry for anything green and succulent. Livestock trailed or transported for long distances without food or water and then suddenly introduced to new pasture may fail to avoid toxic plants and often will eat anything within immediate reach. In general, diagnosis of plant poisoning is based on availability, grazing evidence or presence in the hay, and the existence of plant parts in the rumen contents. Diagnostic lesions are usually lacking, and analytic methods for toxic components are severely limited.

Aconitum, species (monkshood) rarely are a cause of sudden death because of their limited availability. 237
Delphinium, species (larkspur), however, are closely related to monkshood and 238 are responsible for more cattle losses in the western United States than any other poisonous plant. Larkspur grows in dense stands in the mountainous West and is readily consumed, especially during an early stage of growth. Mature stands are less palatable and not as toxic. Cattle poisoned by larkspur often are found close to a stand, collapsed and bloated. Death from the cardiotoxic and neuromuscular blocking effects may occur within a few hours of ingestion. Sheep are less susceptible to larkspur and are seldom poisoned by it, partly because of their different grazing habits.[24] *Asclepias*, species (milkweed) contain either cardioactive glycosides or neurotoxic compounds.[25] The most toxic species reside in the western and southwestern United States. These plants are not very palatable but are somewhat less objectionable when dried. Livestock will graze them in a drought, but the biggest problem is contamination of hay or greenchop. Blue-green algae may cause sudden death in all classes of livestock within minutes of ingestion of toxins from certain neurotoxic species. Toxins from other hepatotoxic species may require 24 hours to induce death. Toxic blooms occur sporadically during certain environmental conditions of

late summer and fall. Diagnosis is usually based on a history of exposure to a concentrated bloom, but some laboratories perform chemical and bioassays.

Calycanthus, species (bubby bush) contain an alkaloid similar in structure and mechanism of action to strychnine. These species are of minor importance to the livestock industry in the Southeast and West but have induced death in cattle. Seeds and other plant parts may be identified in rumen contents. *Cicuta*, species (water hemlock) may induce violent convulsions and death within an hour. Intoxication is most common in early spring, when plants growing along waterways are easily uprooted and the tuberous parts are eaten. A single root system from a large plant can kill a cow. This is one of the most toxic plants in North America, and it has been responsible for the deaths of numerous livestock and humans. *Conium maculatum*, (poison hemlock) grows throughout the United States. Cattle are most sensitive, and sheep are relatively resistant. Poisoning is usually associated with heavily grazed pastures.

Cyanogenic glycosides are present at toxic concentrations in more than 250 plant genera, including *Sorghum*, *Prunus*, *Triglochin*, and *Linum*,. Ruminants are especially susceptible to these glycosides, as they possess the microorganism enzyme systems necessary for rapid liberation of hydrocyanic acid. Death may occur within 15 to 30 minutes of ingestion. Hyperoxygenated venous blood will be cherry red and slow to clot, and rumen contents may have the odor of almond extract. Samples of forage, blood, and rumen contents should be collected immediately, placed in airtight containers, and frozen for analysis. Negative results are often questionable because of the highly volatile nature of hydrogen cyanide. *Drymaria pachyphylla*, (inkweed) has caused sudden death in cattle in the southwestern United States. The differential diagnosis in this part of the country includes anthrax. Diagnosis is based on examination of rumen contents for plant parts.

Halogeton glomeratus, is a soluble oxalate-containing plant that grows best in disturbed soil along roadsides in the western intermountain states. *Sarcobatus vermiculata*, (greasewood) grows in semiarid regions of the West. It also contains toxic levels of soluble oxalate. Unadapted sheep are most frequently intoxicated with these plants, and death may occur within 9 to 11 hours of onset of intoxication. Sudden death results from hypocalcemia and inhibition of cellular respiration. Postmortem findings include hemorrhagic rumenitis, hydrothorax, ascites, and the presence of oxalate crystals in the kidney and rumen wall. *Kalmia*, species (laurel) are an occasional problem in winter or early spring, when they are the only conspicuously green plant available. Laurel grows in the wild in the eastern and western regions of the United States. Death may occur in 12 to 14 hours. Fragments of glossy, leathery leaves may be visible in rumen contents. *Kochia scoparia*, (summer cypress or burning bush) sporadically causes a thiamine-responsive polioencephalomalacia in cattle. *Laburnum anagyroides*, (golden chain tree) is a large ornamental shrub considered to be the second most poisonous plant in Great Britain. It also grows in much of the United States. The shrub contains quinolizidine alkaloids that may induce rapid death from respiratory failure. *Lupinus*, is a genus with about 200 species in North America. There is considerable seasonal variation in toxicity, with the toxic species presenting a problem when plants are very immature or when they have reached the seedpod stage. Acute intoxication and rapid death are likely only when large quantities of seeds are ingested within a short time. Toxic species cause more deaths in sheep than any other plant in Montana, Idaho, and Utah. Improperly cured hay and silage derived from *Melilotus*, species (white and yellow sweet clover) may cause sudden death in cattle when hemorrhage occurs in the cranial vault, pericardial sac, mediastinum, or thorax. Induction of the disease requires consumption of the moldy forage for several weeks to allow sufficient depletion of vitamin K—dependent clotting factors. *Nerium*, species (oleander) are widely cultivated in the South and West. Toxic in the green or dry state, these plants may border hay fields, and significant mortality of livestock may occur when dropped leaves or trimmings are incorporated into forage. Livestock often are poisoned when prunings are mixed with grass clippings and the bitter taste is disguised. Diagnosis is based on evidence of consumption and identification of plant parts in rumen contents.

The genus *Nicotiana*, contains toxic species of wild and cultivated tobacco. Poor palatability usually hinders consumption; however, opportunities for intoxication and death sometimes occur in areas of the West where forage is scarce and in parts of the country where tobacco is cultivated. Nitrate-accumulating plants include certain annuals, weeds, and cool-season crops and grasses. Notable examples include pigweed, lamb's-quarters, Sudan grass, and oat hay. Under the right environmental conditions most plants can accumulate toxic concentrations of nitrate. Plant-associated nitrate poisoning is a serious problem only in ruminants because of the nitrate-reducing ability of rumen microbes. Onset of nitrate intoxication is rapid, and death may result within 6 to 24 hours of rapid ingestion of a toxic dose. Diagnosis is based on a brownish cast to the viscera and blood, together with chemical analysis of serum, aqueous humor, and forage for nitrate concentration.

Acute bovine pulmonary emphysema is associated with an abrupt change from dry range forage to lush green pasture high in L-tryptophan concentration. Less commonly, the pulmonary toxins of *Perilla frutescens*, (perilla mint) can induce dyspnea and death in a few hours. Necropsy reveals incomplete collapse of lungs that are heavy and firm, with froth-filled airways. Histologic examination shows a proliferation of type II pneumocytes. *Phalaris*, species (canary grass) recently were reported to have caused sudden collapse and death of sheep in California.[26] Sheep that had been grazing a field containing canary grass were herded a short distance when six ewes collapsed and died. Bilaterally symmetric, greenish-grey discoloration was seen in the midbrain. The same gross discoloration also was seen in the renal cortex. Microscopic examination confirmed the presence of intracytoplasmic accumulation of this granular pigment. *Solanum*, species (nightshades) grow throughout the United States, especially in waste areas and overgrazed pastures. Rapid ingestion of large quantities of highly toxic fruit can result in coma and rapid death. *Taxus*, species (yew) poisoning in ruminants commonly results in sudden death. Poisoning is most likely to occur when ruminants are pastured adjacent to residential areas where yew is a common ornamental shrub. Diagnosis is based on evidence of exposure and identification of yew leaves in rumen contents. *Xanthium*, species (cocklebur) are most toxic at the cotyledonary stage of growth. These species may induce death in calves within 12 hours of onset of clinical intoxication. Hypoglycemia and centrilobular hepatic necrosis are consistent findings. *Zigadenus*, species (death camas) are of major importance to sheep grazing on western ranges. These plants begin growth in early spring, presenting a significant hazard at this time.[27]

238

239

14.2.10 Miscellaneous Causes of Sudden Death in Horses

Allergic reactions capable of causing sudden death include rupture of warble fly larvae. Warble fly larvae are seldom able to penetrate equine skin, and the fully matured larvae either die or are killed when the horse is saddled or harnessed. Anaphylactic shock results, and pulmonary edema and foam in the airways are found on necropsy. Penicillin or other antibiotics may cause an anaphylactic reaction with a similar outcome.

Perinatal sudden death may occur in foals as a result of meningeal hemorrhage caused by birth trauma. The sudden onset of profuse, watery diarrhea and rapid development of hypovolemic shock characterize colitis-X. A severe necrotic typhlitis is seen at necropsy, with destruction of colonic and cecal mucosa. Diaphragmatic rupture and hernia are associated with violent exercise or trauma, with or without bowel herniation. Electrocution occurs when a horse chews through or comes into contact with an uninsulated hot wire while well grounded. Death is instantaneous, usually with negative necropsy findings. Lightning strike may reveal burning or singeing of skin, hair, or underlying tissue. GI maladies that may cause sudden death include volvulus, intussusception, torsion, incarceration, gastric rupture from grain overload, tympanites, and small intestine rupture from ascarid impaction.

Gunshot wounds may be another cause of sudden death that is surprisingly difficult to verify, as bullet retrieval is necessary to establish the diagnosis. Finding the bullet lodged in tissue is a time-consuming task at best. Heat or work stress is seen in horses in hot, poorly ventilated quarters or in poorly conditioned horses overworked in hot, humid weather. Collapse and coma are followed by death in a few hours. Necropsy reveals skeletal and cardiac muscle damage, GI ulceration, and renal necrosis. In pregnancy, unrecognized and untreated torsion of the gravid uterus may result in sudden death.

Exercise-induced respiratory tract injury may cause sudden death in well-conditioned horses.[28] Epistaxis and pulmonary hemorrhage occur at the peak of training, with most cases being of little concern. However, in fatal cases horses that die immediately after exercise often have subpleural hemorrhages in the caudal lung lobes, and rupture of these hematomas has resulted in extensive intrathoracic hemorrhage and sudden death. Rupture of lung tissue while exercising also may result in fatal hemorrhage.

Serum sickness (acute hepatitis) can be traced to administration of biologics of equine origin 50 to 90 days before the onset of clinical signs. Death may occur within 12 to 48 hours. The main lesion seen is liver necrosis with discoloration and accentuation of the lobular pattern on the cut surface. Fracture of the junction between the basisphenoid and basioccipital bone usually results from rearing over backward and striking the poll on the ground.

14.2.11 Miscellaneous Causes of Sudden Death in Ruminants

Fatal anaphylaxis occurs in sensitized animals after parenteral use of drugs or vaccines. This is most common with the penicillins and vaccines containing gram-negative bacteria or cell walls. Anaphylactic shock also may be an outcome of blood transfusion reactions. Immune-mediated hemolytic anemia (neonatal isoerythrolysis) from ingestion of colostrum-containing antibodies against a neonate's erythrocytes may induce sudden death if the specific antibody concentration is sufficiently high. A sudden death syndrome occurs in feeder cattle on high-concentrate diets. It usually occurs in warmer months and is limited to cattle fed high-concentrate rations for several weeks.[29] A malignant tumor that has been associated with sudden death is the thymoma, or thymic lymphosarcoma, seen most commonly in old goats. It appears as a large, pale, fleshy mass in the cranial mediastinum.[30]

15 Chapter 15 The Peripartum Period

Wendy E. Vaala

Guy D. Lester

John K. House

15.1 THE PERIPARTUM EQUINE

15.1.1 ASSESSMENT OF THE MARE DURING LATE GESTATION

Wendy E. Vaala

Guy D. Lester

It has been estimated that between 25% and 40% of mares that are bred do not produce a live foal.[1–4] Many factors contribute to this poor outcome, including infertility, early fetal loss, abortion, stillbirth, and perinatal death.[2] During late gestation, two of the most important causes of reproductive loss are fetoplacental infection and complications of delivery including dystocia and perinatal asphyxia.[2,5] As mares age, their pregnancy and foaling rates decline and their foals experience higher morbidity and mortality rates and decreased athletic ability.[1,3]

A 1997 National Animal Health Monitoring System (NAHMS) study of 7320 foals estimated a mortality rate of 1.7% within the first 48 hours of a live birth.[6] This includes an estimate of euthanasia and spontaneous deaths. Sepsis, asphyxia, and dysmaturity, including prematurity and postmaturity syndromes, are the leading causes of neonatal foal mortality during the first two weeks of life. Despite dramatic advances in neonatal intensive care, many foals still die, not because their primary problem is untreatable, but because veterinary intervention was delayed, delivery was unattended, neonatal compromise was not recognized in a timely fashion, or critical care was unavailable or not economically feasible. Foals surviving severe peripartum illness often experience increased morbidity associated with chronic infections, suboptimal growth, or developmental orthopedic disease. Therefore the focus of equine neonatology has shifted from a strictly therapeutic approach to a preventative one. This new direction emphasizes assessment of fetoplacental well-being during late pregnancy. The three periparturient events that have the most devastating effect on neonatal survival are hypoxia, infection, and derangement of in utero development. These events can result in behavioral abnormalities, multiorgan system failure, neonatal death, abnormal fetal development, or premature delivery.

Many of the periparturient events associated with increased fetal and neonatal morbidity and mortality have been identified in the mare (Box 15-1). In human obstetrics, prepartum detection of placental dysfunction and fetal distress has become an important factor influencing the management of the last stages of pregnancy and the newborn infant. Following the lead in human perinatology, clinicians are developing biochemical and biophysical techniques for monitoring fetoplacental well-being in the pregnant mare.[7–10] Mares with high-risk pregnancies should be identified early, treated appropriately, and monitored carefully through the birth process. Accurate assessment of fetal well-being is complicated and difficult in the human being. Fetal monitoring in the equine species is less developed and is handicapped by the size of the dam and fetus.

Vaala has suggested that mares experiencing problem pregnancies be assigned to one of three categories: (1) mares with histories of abnormal pregnancies, deliveries, or newborn foals; (2) mares at risk for a problem with the current pregnancy because of systemic illness or reproductive abnormality; (3) mares that have no apparent risk factor but that experience an abnormal periparturient event.[10] A list of important perinatal risk factors is presented in Box 15-2. Ideally, mares with high-risk pregnancies should receive some type of late gestation fetal monitoring or at least be carefully watched during late gestation and attended at the delivery. Personnel attending the delivery of a high-risk foal should be trained in resuscitation techniques.

A variety of biochemical and biophysical parameters can be measured in the late-term mare or fetus. Measurement of maternal progestagen concentrations in plasma may provide an indicator of fetal well-being. Maternal progestagen concentrations are relatively stable between days 150 and 315 of gestation, rising sharply over the remainder of the pregnancy before a large fall in the last 1 to 2 days before parturition. Progestagens are synthesized by the fetus and by the uteroplacental tissues. Two abnormal progestagen patterns have been described.[11–14] In acute maternal illnesses, such as colic or torsion of the uterus, the progestagen concentration declines hours to days before abortion. In these mares progestagen concentration may fall to less than 2 ng/mL.[14] In chronic disease states, such as laminitis or placentitis, there is a premature rise in the plasma progestagen concentration that can persist for weeks before abortion or premature delivery.[11] It has been suggested that a premature increase in maternal progestagens could reflect hastened or precocious fetal maturation. Removal of the stressful event can lead to normalization in progestagen concentrations and the subsequent delivery of a normal-term foal. Progesterone radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA) can be used to quantitate progestagens. Measurement of progestagens may be indicated to determine the need for progestin supplementation.[15]

An ELISA has been developed to measure equine fetal protein, and elevated concentrations were associated with twinning, placentitis, premature placental separation, uterine trauma, and fetal death.[10,16] Additional studies are required before this test can be applied accurately in a clinical setting. Another reproductive hormone that holds promise as a marker of fetoplacental well-being and periparturient complications in the mare is relaxin. The placenta is the primary source of relaxin in horses.[17] In healthy pregnant mares relaxin concentrations increase from about day 80 to a peak of 80 to 100 ng/mL at day 175, which persists until birth.[18,19] In mares with problematic pregnancies, low relaxin levels during late pregnancy have been indicative of placental insufficiency associated with a variety of causes including fescue toxicosis,[20] oligohydramnios, placentitis, and pituitary neoplasia.[21]

15.1.1.1

Box 15-1 Common Causes of Abortion, Stillbirth, and Perinatal Death in Horses

15.1.1.1.1

INFECTIOUS PROBLEMS (IN ORDER OF FREQUENCY)

Fetoplacental infection

Bacterial infections

Viral infections

Fungal infections

Unidentified causes

15.1.1.1.2 NONINFECTIOUS PROBLEMS (IN ORDER OF FREQUENCY)

Neonatal asphyxia not associated with dystocia

Neonatal asphyxia associated with dystocia

Placental edema

Premature placental separation

Twin pregnancies

Contracted foal syndrome

Other congenital malformations

Umbilical cord abnormalities

Placental villous atrophy

From Giles RC, Donahue JM, Hong CB, et al: Causes of abortion, stillbirth, and perinatal death in horses: 3527 cases (1986-1991), *J Am Vet Med Assoc* 203:1170, 1993.

15.1.1.2 Box 15-2 Conditions Associated with the High-Risk Foal

15.1.1.2.1 MATERNAL CONDITIONS

15.1.1.2.1.1 Past History

Foals with neonatal isoerythrolysis, neonatal maladjustment syndrome, congenital malformations

Prematurely born, postterm foals that appear premature, or asphyxiated foals

Dystocia or premature placental separation

Foal rejection

Recent exposure to infectious diseases associated with abortion and stillbirths, such as equine herpesvirus, viral arteritis, *Leptospira* species

15.1.1.2.1.2 Systemic Problems

Fever

Anemia or hypoproteinemia

Endotoxemia

Gastrointestinal crisis, such as large bowel torsion

Malnutrition

Severe systemic infection

Laminitis

Prolonged recumbency from a variety of neurologic or musculoskeletal problems

Excessive medication administration

Prolonged transport before parturition

15.1.1.2.1.3 Reproductive, Mammary Gland, or Localized Problems

Severe endometrial fibrosis

Hydrops allantois or amnii

Purulent vaginal discharge

Prepubic tendon rupture

Pelvic injuries

Agalactia, such as from grazing on fescue pastures

Failure to produce good-quality colostrum

Premature lactation

15.1.1.2.2 ABNORMALITIES OF LABOR OR DELIVERY IN CURRENT PREGNANCY

Premature parturition

Abnormally long gestation

Prolonged labor

Induction of labor

Dystocia

Early umbilical cord rupture, umbilical cord abnormality

Cesarean section

Premature placental separation

15.1.1.2.3 NEONATAL ABNORMALITIES

Meconium-stained fluid or neonate

Placental disease—e.g., placentitis, villous atrophy, edema

Twins

Orphan

Delay in or lack of intake of colostrum

Dysmaturity or prematurity

Exposure to infectious diseases, such as influenza

Trauma (birth, predators, mother)

Adverse environmental conditions

Failure to be up and nursing by 2 to 3 hours of age

Congenital abnormalities

Weakness, poor appetite

Several studies have demonstrated that ultrasound-guided transabdominal amniocentesis and allantocentesis can be performed relatively safely in the late-gestation mare as long as the procedure is performed aseptically and multiple attempts are not made.[10,22] However, the clinical usefulness of fetal fluid analysis in the horse remains to be determined. Studies attempting to relate the phospholipid profile in amniotic fluid with equine fetal lung maturation have been inconclusive to date.[10,22,23] Transabdominal-guided ultrasound amniocentesis has been used to detect experimentally induced equine herpesvirus 1 (EHV-1) fetal infection in utero.[24] This technique holds promise as a diagnostic aid to detect specific fetal diseases and as a potential therapeutic avenue to deliver medication in utero.

Electrolyte concentrations in prepartum mammary secretions may be monitored to predict impending parturition in the mare. As parturition approaches, the mammary concentration of sodium decreases and concentrations of potassium and calcium increase. An elevation in calcium concentration to over 40 mg/dL (10 mmol/L) is considered the most reliable indicator of readiness for birth and may be used to help determine whether elective induction or cesarean section should be performed. The increase in calcium occurs over the last 72 hours of gestation.[25,26] Test strips are commercially available to measure calcium and magnesium concentrations in a field setting (Predict-a-Foal test, Animal Health Care Products, Vernon, CA; FoalWatch kit, Chemetrics, Calverton, VA). The mammary concentration of potassium increases and the mammary sodium concentration decreases over the final 7 days of the gestational period. The mammary concentration of potassium typically exceeds that of sodium between 1 and 5 days before foaling. This has been used by some as a predictor of birth, although a recent study concluded that the use of mammary electrolyte concentrations was not reliable because of individual variability both in raw concentrations and in percent changes.[27]

244 245

An arbitrary scoring system using calcium, sodium, and potassium concentration in the mammary secretions to assess fetal maturity has been described.[26] False-positive results—that is, values that inaccurately predict imminent foaling—have been associated with vaginal discharge, placentitis, and premature lactation. False-negative results occur commonly in mares with systemic illness or in animals that have undergone general anesthesia. In many mares the changes in the electrolytes occur only within hours of delivery, so if monitoring is

not performed frequently, the changes will be missed.[10,27,28] The decision on whether or not to induce parturition in a mare should not be based on the results of this type of testing alone.

Fetal heart rate (FHR) monitoring is routinely used in the human fetus to detect fetal distress, particularly hypoxia, during late gestation and labor and delivery. Doppler ultrasound is the most common technique used for FHR monitoring; this technology has been adapted for use in the mare.[29] First the fetal heart is located using an ultrasound transducer, then the Doppler transducer is placed on the mare's abdominal wall directly over the fetal heart. Fetal movement is detected by a pressure transducer or by a hand placed on the mare's abdomen. Continuous FHR monitoring for at least 10 minutes is preferred to better detect abnormalities in heart rate and rhythm. Use of M-mode echocardiography makes it easier to obtain an FHR measurement because of the rapid motion of the normal equine fetus. Heart rate is normally regular and decreases from greater than 120 beats per minute (bpm) before day 160 of gestation to between 60 and 90 in late gestation.[8,29–31] An average of 10 heart rate accelerations (25 to 40 bpm) was observed in a 10-minute period; 95% of these were associated with fetal movement.[29] Cardiac accelerations in response to fetal movement are an indicator of fetal well-being. Cardiac rhythm should be regular. Persistent bradycardia is associated with fetal distress and is mediated by a vagal response to hypoxemia. Severe tachycardia and arrhythmias have been associated with impending fetal demise. Although persistent fetal tachycardia and bradycardia suggest fetal compromise, normal heart rate alone does not guarantee that the fetus is healthy. Prolonged periods of fetal inactivity in the absence of maternal sedation are also suggestive of fetal compromise.

A fetal electrocardiogram (ECG) may also be used to assess FHR and fetal heart rhythm after day 150 of gestation.[30,31] The procedure is relatively easy to perform. The left arm electrode is placed on the dorsal midline of the mare at the lumbar region, and the left leg electrode is placed 15 to 20 cm cranial to the mare's udder on the ventral midline. The hair should be clipped, and ample gel or alcohol should be placed to ensure good contact of the electrodes. Poor fetal signals may result from poor electrode contact or placement, fetal movement, or electrical interference.[10]

Transabdominal ultrasonography allows noninvasive evaluation of the intrauterine environment and fetal well-being. A biophysical profile (BPP) using five parameters is used in women to evaluate fetal distress late in pregnancy.[32,33] The BPP evaluates the following: fetal tone, fetal movement, fetal breathing, FHR reactivity (i.e., increased FHR during fetal activity), and amniotic fluid volume. The BPP was predicated on the theory that during asphyxia the most complex activity, FHR reactivity, disappears first, followed sequentially by fetal breathing, fetal movements, and fetal tone. Decreases in fetal fluids are associated with chronic intrauterine stress and hypoxia, dysmaturity, and placental insufficiency.[34]

Transabdominal ultrasonography can be used in the mare to evaluate the equine fetus after day 90 when the gravid uterus contacts the ventral abdominal wall. This technique is used more commonly during the second and third trimesters. Recent studies have focused on the development of a modified BPP using FHR reactivity, fetal activity, fetal breathing movements, qualitative and quantitative fetal fluid assessment, evaluation of placental integrity, and measurement of fetal size. Transducers with lower frequencies (2 to 4 MHz) are required because of the deep tissue penetration needed. The mare's ventral midline must be cleaned and clipped from the level of the umbilicus caudally to the mammary gland, and a viscous coupling gel applied. Minimal maternal restraint is usually required. Chemical sedation should be avoided because drugs such as xylazine and detomidine induce fetal bradycardia and retard fetal movement.

In the pregnant mare, transabdominal ultrasonography has been used to detect twins, document fetal position, estimate fetal size using fetal aortic diameter, evaluate fetal activity, evaluate placental integrity, determine fetal

fluid clarity and volume, and monitor FHR and fetal breathing. After 9 months of gestation most fetuses are in an anterior presentation and are unlikely to change that presentation before delivery.[35] The mean fetal thoracic aortic diameter averages between 2.2 and 2.5 cm in horse fetuses.[8] Fetal activity increases with advancing gestational age, and FHR decreases. During late gestation the equine fetus should demonstrate good tone and moderate activity with only brief episodes of inactivity (<20 min). During the last month of gestation the FHR averages between 60 and 90 bpm with transient bouts of tachycardia (25 to 40 bpm above baseline) observed during or immediately after fetal activity. Fetal breathing is characterized by excursion of the diaphragm between the thorax and the abdomen, with accompanying ribcage expansion. Regular breathing movements are observed intermittently in most late-term fetuses. It is difficult to differentiate fetal from maternal breathing movements. The maximum ventral fetal fluid pocket depths average 8 cm for amniotic fluid and 13 cm for allantoic fluid.[8] Excessive fetal fluid accumulation is observed in cases of hydrops. Markedly decreased amounts of fetal fluids have been associated with placental dysfunction and the birth of a dysmature, hypoxic foal. As gestation advances, fetal fluids increase in turbidity. Sudden increases in turbidity may be associated with meconium passage, hemorrhage, or inflammatory debris. Average uteroplacental thickness viewed transabdominally ranges between 8 and 15 mm.[8] Thicker uteroplacental units may indicate placental edema, placental separation, or placentitis. Areas of separation between the uterus and chorion appear as black anechoic areas.

Transabdominal real-time ultrasonography can provide both structural and functional information about the health and environment of the fetus. Because of the depth of penetration required, 2- to 4-MHz transducers should be used. As in other procedures involving ultrasonography, familiarity with the normal appearance of the placenta and fetus is essential to detect abnormalities. Details on how to perform the evaluation can be found in other texts.[29,36–38] In the mare this procedure has been used in late gestation to determine fetal position, estimate fetal size, evaluate the placenta and fetal fluids, detect premature placental separation, and assess fetal movement and viability.[10,37] Overall, fetal activity tends to increase with advancing gestational age; periods of inactivity longer than 15 minutes may indicate the need for further evaluation. A BPP has been developed that uses several parameters to establish an idea of the size and overall health of the equine fetus.[9,29,39] The parameters include fetal weight, as estimated by the fetal aortic diameter (mean 2.1 cm at 300 days' gestation to 2.7 cm at term), heart rate, movement, uteroplacental thickness (mean 1.26 ± 0.33 cm), qualitative allantoic fluid appearance, and allantoic volume estimation. Additional studies are needed to establish the validity of this profile in predicting fetal health or compromise in a larger group of mares.

246

15.1.2 EFFECTS OF PLACENTAL INSUFFICIENCY

The effects of uteroplacental vascular insufficiency on the newborn depend on the severity of placental compromise and the severity and duration of prenatal and perinatal asphyxia. Conditions associated with chronic asphyxia in the large animal fetus include chronic placentitis, villous atrophy, twin and postterm pregnancies, ingestion of endophyte-infected fescue grass by the pregnant mare,[40] and ingestion of ponderosa pine by pregnant cattle.[41]

If decreased uteroplacental blood flow is long-standing, growth is concomitantly inhibited in the fetus. The pattern of growth retardation associated with chronic placental insufficiency is usually asymmetric. This type of growth retardation is characterized by visceral wasting with relative preservation of fetal length and head circumference. Affected human infants are expected to be long and thin, with loss of subcutaneous fat and a large head relative to the body size. The same is probably true in the large animal neonate. It has long been recognized that twin equine neonates and other abnormally small foals tend to have heads that are disproportionately large for their small, wasted bodies.[42]

In placental vascular insufficiency the fetus has the ability to avoid overgrowing its nutrient supply and to maximize organ growth. Under metabolic stress there is a fetal antiinsulin response, with loss of fat and glycogen stores and muscle mass. Associated with the decrease in uteroplacental blood flow is an increase in uterine and fetal vascular resistance, and redistribution of cardiac output, with a greater percentage of blood flow going to organs such as the brain and heart. Unless uteroplacental insufficiency is very severe, brain growth continues at a relatively normal rate. In the human fetus the redistribution of cardiac output also results in decreased blood flow to the lung and kidney and decreased production of fetal urine and lung liquid, two major components of amniotic fluid. A decrease in amniotic fluid volume is therefore associated with chronic fetal asphyxia. The regulation of these adaptations is not completely understood, but corticosteroids, catecholamines, and vasopressin, among others, play a role.[43,44]

It is thought that repeated episodes of hypoxemia during gestation slowly deplete cardiac glycogen stores and impair the ability of the heart to effectively pump blood during subsequent hypoxemic episodes, such as during labor. The newborn with depleted glycogen stores may also be at increased risk of developing hypoglycemia and hypothermia. Meconium aspiration and persistent arterial hypertension in the newborn period are secondary to chronic fetal hypoxia. Immature skeletal ossification, particularly of the carpal and tarsal bones, has also been associated with growth retardation in the foal.[42]

There are certain advantages associated with fetal adaptation to chronic placental insufficiency. Growth-retarded premature human infants have a lower incidence of hyaline membrane disease than babies of the same gestational age who are appropriately sized.[45] Presumably, fetal hormones, such as the corticosteroids and catecholamines that are released in response to nutrient deprivation, stimulate the early maturation of the lung and surfactant system. Accelerated neurologic maturity has also been documented, along with accelerated pulmonary maturity.[46] Therefore the fetus that has been chronically exposed to an adverse in utero environment may be in some ways more tolerant of premature delivery and independent life outside the uterus than the “normal” fetus that is abruptly displaced through induction of labor or cesarean section. The low-birthweight fetus therefore represents a successful adaptation to a nutrient-deprived environment. Its smaller size, decreased metabolic needs, and early organ maturation actually place it at lower risk for hypoxic injury at birth and aid its transition to independent life after delivery.[44] Further discussion of the characteristics, treatment, and prognosis of growth-retarded premature foals may be found in Chapter 19.

Premature lactation, purulent vaginal discharge, previous history of growth-retarded foals, advanced maternal age, and prolonged gestation are problems that should raise the suspicion of chronic uteroplacental insufficiency. The labor and delivery should be attended to minimize the chances of acute asphyxia. The newborn animal should be examined for evidence of growth retardation, infection (particularly in utero acquired pneumonia secondary to placentitis), and metabolic and acid-base derangements. Ample colostrum should be administered, and body temperature and blood glucose should be monitored closely.

One author has suggested that intrauterine growth retardation is unlikely to pose any substantial additional threat to the neurodevelopment of premature human infants unless it is accompanied by chromosome abnormalities, severe perinatal asphyxia, or hypoglycemia, or unless growth retardation is very severe.[47] Human infants that display characteristics of asymmetric growth retardation commonly “catch up” by late infancy or early childhood. Similar observations have been made in the foal. Many mildly to moderately growth-retarded newborn foals have also done well after discharge from the hospital and have grown to a normal size. Problems secondary to an immature musculoskeletal system, such as angular limb deformities, have been the most

common complications noted in these individuals, but careful orthopedic management can result in a successful outcome.

15.1.3 PLACENTITIS

Placentitis is a common cause of reproductive losses in horses in the United States. During the 1998-1999 foaling season in Kentucky, 24.7% of cases of aborted, stillborn, and premature foals were associated with placentitis.[48] The most common cause of placentitis is ascending infection from the lower urogenital tract via a relaxing cervix. A far less common route of infection is the hematogenous avenue, resulting in a diffuse or multifocal placentitis. Most cases of placentitis are the result of bacterial infection caused by typical equine pathogens including *Streptococcus equi* subsp. *zooepidemicus, Enterobacter agglomerans, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa*. In Kentucky and some other regions a slightly different form of placentitis has been recognized and is characterized by focally extensive placentitis located predominantly at the base of the placental horns at the junction of the horns and the body of the placenta. The affected area is covered with thick, tenacious, brown mucoid exudate, and the underlying chorionic villi are necrotic and absent or reduced in size. This form is associated with infection with a group of gram-positive, branching, filamentous *Nocardioform*-like organisms.[48]

246

247

Clinical signs of placentitis include vaginal discharge that may be evident on the mare's vulva, tail, or inner thighs, premature udder development, and precocious lactation. Premature udder development is the result of placental compromise, fetal stress, a precocious increase in maternal progestagen concentration, and enhanced fetal adrenocortical activity. Despite even voluminous vaginal discharge, most mares with placentitis do not become febrile and do maintain a normal appetite. The dam's hemogram and fibrinogen concentration usually remain within normal limits. Transrectal ultrasound can be used to identify placental separation and uteroplacental thickening of the caudal uterine body. This region is most commonly involved in mares with ascending placental infection. Measurement of the combined thickness of the uterus and placenta (CTUP) is established. This measurement increases from approximately 6 mm at 7 months of gestation to 10 to 12 mm at term.[49,50] A measurement greater than 12 mm at 11 months or greater than 15 mm at 12 months is consistent with placental pathology.[49] Measurement of CTUP alone can be misleading, and a recent recommendation involved monitoring of the CTUP by ultrasound along with determination of the maternal progestagen concentrations to give a more accurate assessment of fetal well-being.[11] Transabdominal ultrasonography can be used to evaluate other areas of the placenta to detect loss of placental integrity or increased uteroplacental thickening. Measured using transabdominal ultrasound, the uteroplacental unit should be <16 mm during late gestation. Other signs suggestive of placentitis include increased fetal fluid echogenicity, which may be the result of hemorrhage, purulent exudate of the brown mucoid material associated with *Nocardioform* placentitis.[51] If placentitis is severe enough to alter placental function, reduced fetal movement, loss of heart rate variability, and absolute fetal bradycardia indicate fetal compromise.

Samples of vaginal discharge should be cultured, and Gram stains performed. The goal of maternal therapy is to treat the placental infection and maintain the pregnancy, provided there is no evidence of severe fetal distress or demise. In many cases, because the infection is of long duration, the fetus has been chronically stressed and therefore is relatively mature for its gestational age and better prepared to tolerate premature birth. If placentitis is suspected, after delivery the foal should be considered a high-risk individual. Commonly encountered problems in the newborn foal that was exposed to placentitis are pneumonia, uveitis, growth retardation, incompletely ossified bones, and, sometimes, systemic sepsis.

15.1.4 MANAGEMENT OF THE HIGH-RISK LATE-GESTATION MARE

Each mare should receive a complete physical examination, and a complete foaling history should be obtained. She should be evaluated regularly for clinical signs of impending parturition (sacroiliac ligament and perineal relaxation, mammary development, and mammary secretion electrolyte concentration). The reproductive tract may be evaluated by rectal palpation, and transabdominal ultrasonography may be performed at regular intervals to detect changes in the fetus, fetal fluids, or placenta. Prolonged periods of starvation are best avoided to prevent maternal hypoglycemia.[10] Estimation of progestin concentrations in the maternal circulation, using a commercial progesterone assay, is recommended.[11]

When treating the pregnant mare for any medical or surgical condition, there are two patients to consider: the dam and the fetus. Any illness or disease that affects the mare's cardiovascular system has the potential to affect placental perfusion and the integrity of the fetoplacental unit. Hypotension, endotoxemia, and hypoxemia are examples of conditions that can alter uteroplacental blood flow and jeopardize the pregnancy. Diseases that stimulate prostaglandin production have the potential to initiate labor and delivery. Illnesses that produce prolonged periods of anorexia in the late-term mare can also lead to premature delivery. The effect of various drugs on the placenta and fetus should be considered when treating the pregnant mare. If delivery is not imminent, then many drugs will pass through the placental and fetal circulation and be cleared by the maternal liver and kidneys. Because of the epitheliochorial nature of the mare's placenta, some drugs will not cross the placental barrier at all. If drugs are administered to the mare and the fetus is delivered shortly thereafter, then the neonate must rely on its renal and hepatic function to process, degrade, and excrete those drugs. In most instances, as long as fetal well being and placental integrity are closely monitored, the goal of most therapies is to treat the maternal condition and maintain the pregnancy as long as possible to achieve an acceptable degree of fetal maturation. Early data derived from late pregnant mares indicated that penicillin and gentamicin did not readily cross the fetal membranes.[52,53] However, recent studies using microdialysis probes inserted into the allantoic fluid of normal mares reported therapeutic concentrations of penicillin and gentamicin in the allantoic fluid after 22,000 IU/kg of potassium penicillin G (intravenous [IV] administration q6h) and 6.6 mg/kg gentamicin (IV q24h).[54] Studies in two mares with experimentally induced bacterial placentitis again confirmed passage of both drugs across the placenta. The combination of trimethoprim-sulfadiazine (30 mg/kg orally [PO] bid) and the phosphodiesterase inhibitor pentoxifylline (8.5 mg/kg PO bid) also readily crosses the fetal membranes in both healthy mares and in animals with experimental placentitis.[53,55] In many cases medical treatment of the placental infection and prolongation of pregnancy is associated with a good outcome. Maternal treatment includes systemic antibiotics, flunixin meglumine, and altrenogest.[10] Because of the usual presence of mixed gram-positive and gram-negative placental and fetal infections, a broad-spectrum antibiotic that reaches therapeutic levels in the fetus and fetal fluids should be selected. Therapeutic options include penicillin and gentamicin, trimethoprim-sulfonamide, and ceftiofur. Low doses of flunixin can be administered to decrease inflammation and prevent prostaglandin-mediated induction of delivery. Regumate (altrenogest) (10 to 20 mL PO q24h) is given to help maintain the pregnancy. If there are large areas of placental thickening, IV dimethyl sulfoxide (DMSO) (0.5 to 1 g/kg) can be administered to decrease placental edema. Pentoxifylline has also been administered in attempts to improve placental perfusion.

If premature delivery appears unavoidable, then one or two doses of maternal steroids can be used with the hope of stimulating and accelerating fetal lung maturation through enhanced surfactant production. In the high-risk mare, it is very important that the delivery be attended by knowledgeable personnel and that all supplies, drugs, and equipment required for diagnosing and correcting a dystocia and stabilizing the mare and foal be organized and close at hand. A spontaneous, vaginal delivery is generally preferred in the high-risk mare, because of both

the profound problems associated with the untimely delivery of a premature foal and the complications sometimes associated with induced labor or cesarean section.[56,57] (See Chapter 19, Prematurity.) There are instances, however, when an induced birth or cesarean section is indicated or preferred.

Induction of parturition should be considered with the following:

- Severe fetal distress noted on prenatal assessment
- Evidence of premature placental separation or a history of premature placental separation associated with dead or asphyxiated foals
- Hydrops allantois and/or amnion
- Unproductive stage I labor
- Uterine inertia
- Impending prepubic tendon rupture
- Life-threatening maternal illness

Indications for cesarean section may include the following:

- Pelvic injury or abnormality resulting in obstruction of the birth canal
- Gastrointestinal crisis requiring surgery
- Severe dystocia
- Insufficient, thickened placenta associated with fescue toxicity in the mare
- Catastrophic and terminal illness or injury in the mare, such as gut rupture or fractured limbs

If induction of parturition or cesarean section is elected, every effort should be made to ensure that the fetus is mature and is ready to be born; the usual result of induction at an inappropriate time is a nonviable newborn. Three essential criteria are a gestation of longer than 330 days, good-quality colostrum in the udder, and softening of the cervix.[56] The scheduling needs of the veterinarian or owner should never be the only criterion used for determining the timing of delivery. A slow continuous oxytocin infusion administered at a rate of 1 unit/minute usually results in delivery within 20 to 40 minutes.[10] Alternatively, multiple IV or intramuscular injections of 10 to 20 units of oxytocin every 10 minutes have been recommended.[56,58] Other investigators have shown that smaller IV doses of oxytocin (2.5 IU administered every 15 to 20 minutes until rupture of the chorioallantois or a total of 20 IU of oxytocin has been administered) is an effective, and perhaps more physiologic, method of induction.[59]

Induction of parturition in the mare has been associated with more violent, painful contractions than spontaneous labor and a higher incidence of premature placental separation and neonatal asphyxiation. Cesarean section also predisposes to neonatal peripartum asphyxia. Maternal hypotension secondary to general anesthesia and the weight of the maternal abdominal contents on the aorta and vena cava may both compromise uteroplacental circulation. For further details concerning anesthesia of the late-term mare, the reader is referred to other texts.[60,61] The management of a mare with hydrops amnion was recently described.[62] Abdominal support was used

along with nonsteroidal antiinflammatory drugs and altrenogest to maintain the pregnancy up until day 321, when spontaneous delivery occurred. The delivery was complicated by uterine inertia, maternal postpartum hypovolemic shock, and cardiac arrhythmias, but both mare and foal survived.

15.2 THE PERIPARTUM RUMINANT

John K. House

The peripartum period is a high-risk period for the fetus and dam. Approximately 5% to 10% of the annual calf crop and 15% to 20% of the annual lamb crop in the United States dies before weaning.[63,64] Between 50% and 70% of neonatal mortality occurs in the first 3 days of life, with dystocia, starvation, and hypothermia responsible for 50% to 60% of these losses.[64,65]

Reduced fetal viability often reflects mismanagement of maternal nutrition and/or the maternal environment during the last trimester of pregnancy and/or the prepartum and peripartum periods. Investigation of perinatal morbidity and mortality should begin with assessment of maternal management. Some of the more common causes of stillbirth and perinatal mortality are listed in Box 15-3.

Forty percent to 60% of stillbirths are associated with dystocia. Calves that survive dystocia are more likely to have edema of the head and tongue, making suckling difficult. They are also weak and exhausted and likely to be recumbent for a longer period of time and expose themselves to more fecal pathogens.[66] Dystocia affects the uptake of immunoglobulins by the calf, and calves that survive dystocia are more likely to become sick in the first 45 days of life.[67] Maternal variables correlated with dystocia and consequently calf mortality at birth include parity and conformation. Dystocia and stillbirths in heifers are most commonly secondary to fetopelvic incompatibility. Fetopelvic incompatibility accounts for a lower proportion of dystocias in multiparous cows, but weak labor secondary to hypocalcemia, uterine torsion, and incomplete cervical dilation are more common in older cows.[68] In a large study of Holstein calving records, 8.3% of calves born to heifers were stillborn compared with 3.6% of calves born to multiparous cows.[69] Dam pelvic diameter is an important determinant of dystocia for heifers.[70] Pelvic measurements can be used to identify abnormally small or abnormally shaped pelvises. Large frame size of the dam correlates with a reduced risk of dystocia; however, continued selection for large frame size tends to select for larger birthweight and dimensions of calves.[71] Age at first calving for heifers is not correlated with risk of dystocia as long as heifers are fed and managed to achieve appropriate growth and stature before calving.[72–74] The risk of dystocia in heifers is increased by poor nutrition in the last trimester.[75] Appropriate nutrition and management of replacement heifers to achieve appropriate size and stature at parturition reduces maternal and neonatal losses by reducing the incidence of dystocias. Maternal consequences associated with calving difficulty and delivery of a stillborn calf include decreased milk production and reduced reproductive efficiency. Reductions in milk production ranging from 100 to 400 kg have been reported to be associated with the birth of a stillborn calf. If the stillborn calf is delivered by cesarean section, the reduction in milk yield is in the order of 300 to 500 kg.[69] Delivery of a stillborn calf is also associated with depressed conception rates, increased services per conception, and delayed conception.

Use of calving ease bulls over primiparous cows helps to reduce the incidence of dystocia and subsequently mortality during parturition. The heritability of calving ease is relatively low; estimates of maternal calving ease range from 0.03 to 0.24,[68,76,77] and paternal heritability is approximately 0.147. Despite the relatively low heritability of calving ease, selection for calving ease should not adversely affect other production parameters in dairy cattle, as the genetic correlation between calving ease and other dairy production traits are generally close to

0.[68] Calving ease evaluations are intended to increase the use of artificial insemination (AI) for heifers. To facilitate sire selection most breed associations provide guidelines regarding calving ease or expected progeny difference for calf birthweights. An example of such a scheme is the calving ease and reliability values assigned to AI Holstein bulls. In this system the calving ease score is the expected percentage of difficult births predicted for calves delivered by primiparous cows.[78] The reliability score provides an indication as to the number of births that were considered in deriving the calving ease score. The higher the reliability score, the larger the number of observations the calving ease score is based on and the more likely it is that the calving ease prediction will accurately reflect the outcome.

Management variables that influence the risk of dystocia and perinatal mortality include stocking density of preparturient cows, timing of calving, and cow grouping. In a study of 123 beef herds the dystocia rate was highest for cows housed in a barn and decreased progressively through barn-and-yard, barn-and-pasture, and pasture-only calving location categories.[79] The most common cause of dystocia in penned heifers was vulval constriction, whereas dystocias in paddocked heifers were most commonly associated with malpresentations.[80] Calving beef heifers 6 weeks before cows has been recommended to allow the heifers longer to recover and conceive after calving than cows.[81] In a herd level comparative study this practice was associated with a higher incidence of dystocia and stillborn calves.[79] Presumably because of better nutritional management, heifer dystocia rate is reduced the longer heifers are maintained as a separate group from cows before calving.[79]

Fetal variables that influence the risk of mortality include sex, size, and number. Calves born to primiparous cows, twins, and bull calves are more likely to die at birth than calves born from multiparous cows, single calves, and heifer calves.[82,83] Low and high birthweight calves are at greater risk of mortality than average birthweight calves.

[82] Small calves experience greatest mortality at parities greater than one, and large calves at first parity.[72] Fetal viability may be compromised in utero by a number of infectious agents. Common infectious agents associated with abortion and or birth of weak calves are listed in Box 15-3. Manifestations of disease in the newborn are dependent on the time of exposure to the infectious agent.

Environmental stress before or around the time of parturition can compromise the fetus or neonate. Heat stress affects fetal viability by impeding calf growth in the last trimester of pregnancy[84] and by depressing colostral quality[85] and immunoglobulin transfer.[86] Uterine blood flow and placental mass are reduced and endocrine profiles altered when cattle are heat stressed during the last trimester of pregnancy. Heat stress during the last 3 weeks of pregnancy lowers dry matter intake, contributing to a negative energy balance at this time, promoting mobilization of body fat and ketogenesis. Transfer of immunoglobulins to colostrum is impaired, and the concentration of protein, casein, lactalbumin, fat, and lactose in colostrum is reduced.[85] Cold, windy, and wet conditions also adversely affect calf survival. The magnitude of the effect of climate on neonatal survival depends on the age of the dam, sex and size of the calf, and incidence of dystocia in the herd.[82] Cold stress sufficient to cause hypothermia in calves leads to subcutaneous hemorrhages and delayed absorption of colostral immunoglobulins.[87]

Maintenance of adequate nutrition throughout pregnancy is essential to provide for the growing fetus and to maintain a healthy dam capable of delivering and nursing the fetus. Pregnancy toxemia, hypocalcemia, protein energy malnutrition, micronutrient deficiencies, and obesity may all impair the health of the fetus directly, or indirectly by affecting the health or capacity of the dam to deliver the fetus. Protein energy malnutrition and copper deficiency have been associated with impaired fertility, weak calves, and high calf mortality.[88]

249 250

15.2.2 Assessment of Fetal Viability

Fetal viability is rarely evaluated during the prepartum period in production animals, but it is a serious consideration when the prepartum dam is diseased or debilitated. Assessment of fetal viability is diagnostically challenging, but a number of methods are available to evaluate the fetus and fetal environment. During the physical examination of cattle, uterine blood flow, uterine tone, and presence of a vaginal discharge may be evaluated via rectal palpation and a vaginal speculum examination. Reduced fremitus in the uterine arteries and increased uterine tone may be appreciated by rectal palpation after fetal death. Abdominal ultrasound is useful for examining the uterus, placenta, and fetuses of small ruminants. The uterus and placenta of cattle can be examined by transrectal ultrasound, but examination of the fetal calf via transrectal or transabdominal ultrasound is often compromised by limited access. Fortnightly ultrasound of the uterus and placenta of recipient cows carrying cloned calves is conducted to detect evidence of hydroallantois and placental edema in these high-risk pregnancies.[89] After fetal death, some of the following may be observed: thickening of the uterine wall, increased echogenicity of chorioallantoic and amniotic fluid, altered fetal posture, altered contour of the amnion, and reduced definition and ultimately reduced size of the caruncles.[*] Examination of the fetus may reveal gross congenital abnormalities, and ultrasound of the fetal chest allows visualization of a beating heart and determination of FHR. The normal heart rate of full-term lambs is 108 to 126 bpm.[90] Measuring the heart rate of fetal calves is more difficult than in small ruminants but can be achieved via transabdominal Doppler using a 1.5-Mhz probe. The normal heart rate of full-term calves is 90 to 125 bpm.[91] In human medicine FHR is used as a measure of fetal viability. FHR accelerations associated with fetal movement are considered a sign of fetal well-being, and persistent bradycardia or tachycardia a sign of fetal stress.[92] Normal FHR patterns of ruminants need to be characterized in more detail before FHR measurements are used for prenatal clinical assessment of ruminant fetal well-being.[93]

Fetal loss associated with abnormal placentation occurs sporadically and is reflected by alterations in volume and composition of allantoic and amniotic fluid. In a study of 60 cases of bovine hydrops, 88% were hydroallantois, 5% hydramnios, and 7% a combination of both.[94] Hydroallantois is often associated with disease of the uterus and hydramnios with genetic or congenital defects of the fetus (Dexter cattle with bulldog calves, Angus calves with osteopetrosis, Guernsey calves with pituitary hypoplasia or pituitary aplasia).[95] The concentration of sodium and chloride in allantoic fluid of cattle during the last 12 weeks of gestation is normally low (Na = 52 ± 20 mmol/L and Cl = 17 ± 11 mEq/L) and concentration creatinine concentration is high (1224 μg/mL ± 458).[96] With hydroallantois, allantoic fluid sodium and chloride concentrations rise toward extracellular fluid concentrations (Na = 116 ± 13 and Cl = 81 ± 12 mEq/L), and allantoic creatinine concentration decreases (193 ± 73 μg/mL).[96] Normal amniotic fluid has electrolyte concentrations similar to those of plasma (Na = 132 ± 7 and Cl = 115 ± 8 mEq/L) and a lower creatinine concentration than allantoic fluid (70 ± 26 μg/mL).[96] Cows with hydroallantois are also often hyponatremic and hyperglycemic.[94,97]

Estrone sulfate is a marker of a viable fetoplacental unit and has been used to assess fetal viability in cattle.[98] Estrogen synthesized by embryonic tissue is converted to estrone sulfate by the endometrium, which contains the enzyme sulfotransferase. Estrone sulfate assays can be used to diagnose pregnancy in small ruminants after 50 days[99] and in cattle after 100 days.[100] Estrone sulfate may be measured in plasma or milk[84,100]; baseline values are low after fetal loss, regardless of the stage of pregnancy. Compromise of the fetoplacental unit reduces estrone sulfate production. In a study of the effects of heat stress on pregnant cattle, plasma estrone sulfate concentrations were significantly lower throughout pregnancy in cows that gave birth to low-birthweight calves.[84] Plasma concentrations of estrone sulfate rise slowly during the second trimester of pregnancy from 0.74 ng/mL to 3.66 ng/mL from day 90 to day 210 of pregnancy. The last trimester of pregnancy is associated with a rapid rise in the concentration of estrone sulphate to 13.36 ng/mL at approximately 10 days before parturition.[101]

In human medicine, diagnosis of surfactant deficiency is based on the ratio of two phospholipids in amniotic fluid, lecithin (L) and sphingomyelin (S). If the L/S ratio is greater than 2, the surfactant system is mature and respiratory distress syndrome is rare.[102] The L/S ratio in amniotic fluid collected from cattle may also be used to assess surfactant system maturity,[103] providing a measure of readiness for birth, but is rarely employed in clinical veterinary medicine. Crude surfactant harvested from bovine lungs at a slaughterhouse has been used intratracheally with calves that appeared to be in respiratory distress shortly after birth.[104]

* Dr. JD Rowe, UC Davis, personal communication.

15.3 INDUCTION OF PARTURITION IN RUMINANTS

Manipulation of parturition may be considered for maternal, fetal, or management reasons. Fetal viability after induced parturition is variable among species. The viability of calves induced within 14 days of anticipated calving date is good.[105] Viability of lambs and kids induced more than 5 days before anticipated parturition date is poor.[95] Absorption of colostral immunoglobulins by premature calves is reduced, so colostral transfer should be monitored closely in induced neonates.[106] Induction of parturition or cesarean section is often necessary to prevent mortality of small ruminants with pregnancy toxemia.[107] Fetal viability is often improved by induction of parturition with dexamethasone; however, delivery of the fetuses via cesarean section is often necessary because of the debilitated state of the dam. Secretion of glucocorticoid hormones from the adrenal cortex increases markedly during the final days of gestation. The prenatal increase in fetal glucocorticoid secretion plays an important role in the cascade of

endocrine events leading to parturition and stimulates maturational events in the lungs, liver, kidney, and gastrointestinal tract in preparation for postnatal life.[108]

Steroids stimulate production of surfactant phospholipids by alveolar type II cells, enhance the expression of surfactant-associated proteins, reduce microvascular permeability, and accelerate overall structural maturation of the lungs.[109] Administration of 10 mg of flumethasone and 25 mg of dinoprost to pregnant cows 30 hours before elective cesarean section increases the L/S ratio, improving lung function and reducing complications associated with respiratory acidosis in the calf.[110] Induction of parturition has been used to reduce the incidence of dystocia in herds or breeds experiencing a high incidence of dystocia associated with fetomaternal disproportion.[111] Large birthweights are strongly correlated with fetomaternal disproportion.[112,113] Induction of parturition within 14 days of anticipated calving date is associated with good calf viability and a 3.2-kg reduction in birthweight of beef calves.[105]

250
251

Exogenous glucocorticoids, prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), or a combination may be used to induce parturition in cattle (dexamethasone 20 to 30 mg alone or in combination with 25 mg $PGF_{2\alpha}$) and in sheep and goats (10 to 20 mg dexamethasone and/or 15 mg $PGF_{2\alpha}$).[95] Glucocorticoids are more effective than prostaglandin for inducing parturition in sheep.[114] A lower incidence of dystocia and higher viability of calves has been reported in cattle induced with glucocorticoids compared with cows induced with prostaglandin.[115] Cows treated with dexamethasone or prostaglandin within 14 days of anticipated calving date usually calve within 72 hours of treatment.[105] Combination of dexamethasone with prostaglandin increases the efficacy and reduces the interval to parturition (36 hours).[116,117] Retention of fetal membranes is a common complication of induced parturition in cattle.[118] Retention of fetal membranes may be associated with reduced first service conception and subsequent pregnancy rates.[119] Treatment of cows with prostaglandin at calving was reported to reduce the incidence of retained fetal membranes,[120] but subsequent studies have failed to support this.[116,121] Induction of cattle by administration of 25 mg of triamcinolone (Opticortinol) at day 270 followed by treatment with dexamethasone and prostaglandin 6 days later appears to reduce the incidence of retained fetal membranes associated with induction.[118,122] Coliform mastitis is an uncommon complication observed after induced parturition.[123]

16 Chapter 16 Perinatal Adaptation, Asphyxia, and Resuscitation

Guy D. Lester

Wendy E. Vaala

John K. House

16.1 PERINATAL ADAPTATION

John K. House

At birth the fetus must successfully make a series of structural and physiologic changes to survive. Perinatal mortality is often attributable to cardiovascular, pulmonary, thermoregulatory, or metabolic physiologic abnormalities. Dystocia and severe birth asphyxia compromises physiologic transitions, increasing the risk of neonatal mortality. Compromised neonates that survive the birth process are less likely to consume adequate colostrum and are subsequently more likely to die of hypothermia and infectious diseases. A good review of physiologic mechanisms of adaptation at birth is presented by Kasari.[1]

The placenta functions as the respiratory organ of the developing fetus; efficiency of oxygen transfer to the fetus is increased by the high oxygen affinity of fetal vs. adult hemoglobin.[2] In utero the potential spaces of alveoli and the tracheobronchial tree are distended with fluid secreted by pulmonary tissue.[3] Oxygenated blood is delivered to the fetus via the umbilical vein, which anastomoses with the portal vein near the liver, and approximately two thirds of the blood flow is shunted via the ductus venosus directly into the caudal vena cava.[1] The caudal vena cava drains into the right atrium, where over 50% of the volume shunts directly into the left atrium via the foramen ovale.[1] The relatively hypoxic in utero environment causes constriction of pulmonary vessels and dilation of the ductus arteriosus.[1] Because pulmonary arterial resistance is higher than systemic arterial resistance, nearly 70% of pulmonary artery flow is shunted via the ductus arteriosus into the aorta, with the remainder perfusing the lung.[4] Left ventricular output is distributed to the systemic circulation via the aorta. The two umbilical arteries arise from the aorta in the region of the last lumbar vertebra to carry predominantly venous blood back to the placenta via the umbilicus.

At birth some of the lung fluid is evacuated through the trachea during spontaneous delivery.[5] When the umbilicus ruptures, asphyxia triggers reflex gasping, respiratory movements, and increased peripheral vascular resistance.[4] The majority of lung fluid is absorbed through alveolar walls in the initial stages of ventilation.[5] This mechanism is prompted by activation of adrenaline-mediated β-adrenergic receptors in the pulmonary epithelium.[6] The rapidity of lung fluid absorption by the body is optimized at thoracic pressures between 35 and 40 cm H_2O.[5] Pulmonary ventilation reduces pulmonary vascular resistance, promoting perfusion of the ventilated alveolar tissue.[1] The increased O_2 saturation of blood stimulates closure of the ductus arteriosus within 4 to 5 minutes of birth.[4] The foramen ovale functionally closes within 5 to 20 minutes of birth when increased pulmonary venous return raises blood pressure in the left atrium, reversing the right-to-left shunt.[4] The septum secundum, a thin fold of tissue that lies in close apposition to the foramen, acts as a valve closing the opening. Healthy calves have mean pulmonary arterial pressures ranging from 40 to 82 mm Hg immediately after birth, declining to 22 to 25 mm Hg by 2 weeks of age.[7] Systemic arterial pressure is approximately 100 mm Hg, and arterial saturation is greater than 90%.[1]

Transient mild metabolic and respiratory acidosis is observed after rupture of the umbilical cord as a result of anaerobic glycolysis in poorly perfused tissues during the transition between placental oxygen delivery and establishment of respiratory function. The mild acidosis is normally corrected within 1 to 4 hours of birth.[8] Anatomic closure of the foramen ovale and ductus arteriosus may take several weeks.[4] Normal blood gas values for the calf during the immediate postpartum period are presented in Table 16-1.

Dystocia is commonly associated with prolonged hypoxia and acidosis. Hypoxia and acidosis maintain constriction of pulmonary arterioles, and the subsequent maintenance of high pulmonary vascular resistance favors continuation of in utero right-to-left vascular shunts, which contributes to systemic hypoxia. After dystocia neonates are less active, slow to stand, slow to nurse, and prone to hypothermia and hypogammaglobulinemia. The normal duration of stage 2 labor (from appearance of fetal membranes at the vulva to delivery of the fetus) in ruminants is generally shorter in multiparous animals (approximately 30 minutes) than primiparous animals (approximately 60 minutes).[9] Fetal viability is improved with early intervention; multiparous animals should be assisted after 30 to 60 minutes of stage 2 labor, and primiparous animals after 60 to 90 minutes.[10]

The range in ambient temperatures over which newborn animals are able to maintain homeothermy is much narrower than in growing or adult animals. Neonates are more susceptible to fluctuations in environmental temperature because of their large surface area—to-mass ratio, evaporation of amniotic fluid, and limited caloric reserves. Starvation and hypothermia is the second leading cause of death of neonatal lambs.[11] Neonatal mortality increases with decreasing ambient temperature and with increasing precipitation on the day of birth.[12] Thermoneutrality is maintained by shivering and metabolism of brown adipose tissue. Normally at birth blood glucose concentration in calves ranges between 50 and 60 g/dL, rising to 100 mg/dL within the first 24 hours of life.[1] Lambs born in warm weather can survive for up to 4 days without supplemental nutrition. Severe weather stress may increase energy requirements by 500% and deplete the energy reserves of newborn lambs in 6 to 16 hours.[13] Starvation exacerbates the effects of environmental stress by reducing the available substrates for heat production, and energy depletion leads to hypoglycemia. Administration of glucose to hypothermic neonates before and during warming is important to avoid deaths from cerebral hypoglycemia induced by increased use of glucose by peripheral tissues.[14] Warming hypothermic lambs by immersion in 38 ° C water is more efficient than infrared lamps or wrapping them in cotton cloth.[15]

252

253

Table 16-1 Arterial and Venous Blood Gas Values for Newborn Calves

	Parameters					
	Calf Age	pH	Po_2	Pco_2	HCO_3^-	Base Excess
Venous*	1 hour	7.219 (0.05)	N/A	41 (5.9)	24.2 (2.7)	–2.9 (3.2)
Arterial†	1 hour	7.3 (0.05)	58.43 (11.61)	50.40 (5.27)	23.52 (2.78)	N/A

Values represent mean with standard deviation parenthesis. *N/A,* Not available.

* Blood was taken from the brachial artery while the calf was in lateral recumbency (N = 30).[73]

† Blood taken from the jugular vein immediately post partum.[8]

No intrauterine transfer of immunoglobulin (Ig) occurs in ruminants; hence, at birth, neonatal ruminants are agammaglobulinemic and immunologically naive. Infectious disease is the leading cause of morbidity and

mortality in calves greater than 3 days of age.[16] Failure of passive transfer (FPT) increases the risk of neonatal mortality.[17] Colostrum provides a concentrated source of energy and immunoglobulins. Immunoglobulins are concentrated in colostrum by an active, receptor-mediated transfer of IgG_1 from the blood of the dam across the mammary gland secretory epithelium beginning several weeks before parturition.[18] Colostral IgG_1 concentrations may be 5 to 10 times the maternal serum concentrations. IgM, IgA, and IgG_2 concentrations in colostrum are much lower.[19] The large numbers of leukocytes also contribute to providing passive immunity to the newborn.[20] Methods of assessing passive transfer and management of FPT are discussed in detail in Chapter 53.

16.2 ACUTE ASPHYXIA IN THE NEONATE

Wendy E. Vaala

Guy D. Lester

Peripartum asphyxia can lead to encephalopathy, ischemic renal failure, and varying degrees of gastrointestinal (GI) dysfunction, the most severe form being necrotizing enterocolitis (NEC). The encephalopathy is most commonly referred to as *hypoxic ischemic encephalopathy* (HIE). The diagnosis of peripartum asphyxia syndrome relies on prepartum transabdominal ultrasonography of the fetoplacental unit, postpartum placental and neonatal foal examination, and immediate assessment of creatinine and presuckle glucose in the foal after delivery. Patient survival may depend on management of central nervous system (CNS), GI, and renal dysfunction.

Any process that results in impairment to placental blood flow or gas exchange can produce asphyxia. These changes in moderation are both normal and critical for postnatal adaptation through a phenomenon known as *ischemic preconditioning*. Essentially, brief episodes of ischemia, as can occur with myometrial contractions, induce partial protection against subsequent episodes of severe ischemia. This is likely mediated through inducible nitric oxide and can also be triggered by hypoxia and volatile inhaled anesthetic agents.[21] Disease develops when episodes of ischemia and/or hypoxia are severe or prolonged. Asphyxia is a multifactorial disease process that develops when tissue oxygenation is disrupted. It is most commonly encountered when pregnancy and labor are complicated by problems resulting in impaired oxygen delivery to fetal tissues, on either a short-term or a long-term basis. Peripartum asphyxia has been associated with rapid, seemingly uncomplicated deliveries, dystocia, induced delivery, cesarean section, premature placental separation and other placental abnormalities, umbilical cord abnormalities, twinning, meconium staining, postdate pregnancy, and severe maternal illness.[22] Asphyxia may also occur in the neonatal period; causes include severe hemorrhage, resulting in hypovolemia and shock, and severe cardiorespiratory dysfunction, as in severe pneumonia, cardiac malformations, pulmonary hypertension, and airway obstruction.

The overall incidence of the condition in the foal is not known, because of the high incidence of unmonitored and unobserved deliveries and the diagnostic confusion of asphyxial problems with other perinatal problems.[23] In a recent study of causes of equine perinatal death, complications of birth, including asphyxia, dystocia, and trauma, were listed as the second most common cause of death after infection (19% of 3527 cases). This figure does not include acute placental or umbilical cord abnormalities, problems that also could have caused acute fetal asphyxiation.[23]

Peripartum asphyxia produces HIE, ischemic renal failure, and varying degrees of NEC. Diagnosis relies on prepartum transabdominal ultrasonography of the fetoplacental unit, postpartum placental and neonatal foal

examination, and immediate assessment of creatinine and presuckle glucose in the foal after delivery. Patient survival depends on management of CNS, GI, and renal dysfunction.[24]

16.2.1 Pathophysiologic Considerations

Perinatal asphyxia describes an episode of impaired oxygen delivery to cells from hypoxemia (decreased oxygen concentration in blood) and or ischemia (decreased blood flow to tissues) around the time of birth. Pure hypoxemia implies a decrease in oxygen concentration in the blood with preservation of blood flow, which allows organs to respond by increasing their efficiency in extracting oxygen from the circulation. The effects of hypoxemia and ischemia are not identical, but they are difficult to distinguish clinically. Ischemia is far more devastating and results in anaerobic metabolism, increased lactate concentrations, and intracellular acidosis and is a preamble for reperfusion injury. Metabolites of anaerobic metabolism, such as lactic acid, cannot be removed from the tissues until blood supply is restored. As a result, severe acidosis may develop locally, which interferes with cellular function and may cause irreversible cell damage.

In general terms, preterm animals are far more tolerant of periods of hypoxia than adult animals. In utero the mammalian fetus adapts to a relatively hypoxic environment by increased oxygen affinity of fetal hemoglobin, increased ability to extract oxygen from the blood, and a greater tissue resistance to acidosis. Hemoglobin in the fetal foal is structurally similar to adult hemoglobin, but the fetal erythrocyte carries increased concentrations of 2,3 diphosphoglycerate, causing a leftward displacement of the sigmoidal hemoglobin-oxygen dissociation curve and an increased affinity for oxygen.[25] Fetal compensatory mechanisms against increasing asphyxia include bradycardia, decreased oxygen consumption, anaerobic glycolysis, and reflex redistribution of blood flow with preferential perfusion of the brain, heart, and adrenal glands at the expense of circulation to kidneys, gut, liver, lungs, and muscle.[26] The shunting of blood away from kidneys and the gut during in utero asphyxia is likely centrally mediated via the α-adrenergic component of the sympathetic nervous system.

253

254

The extent of tissue injury depends on whether the asphyxial insult is acute or chronic, or partial or complete, and whether the neonate is premature or full term. Severe in utero hypoxia can lead to prolonged hypoperfusion and reduced metabolism with an associated and sequential loss of fetal reflexes, with the most oxygen-demanding fetal activities disappearing first. Fetal reflexes are lost in the following order: (1) fetal heart rate reactivity (the ability to increase heart rate in response to fetal activity), (2) fetal breathing, (3) generalized fetal movements, and (4) fetal tone.

An episode of perinatal asphyxia may not result in immediate cell death but can induce a complex cascade of events that can lead to delayed damage.[27] The two key processes of neuronal injury after asphyxia are neuronal necrosis and apoptosis.[28] After asphyxia there is a latent phase that occurs with reperfusion; this phase involves an initial recovery of cerebral energy metabolism. A secondary phase takes place between 6 and 15 hours after the asphyxial insult and is characterized by the accumulation of cytotoxins, seizures, cytotoxic edema, and failure of cerebral oxidative metabolism. Without sufficient energy, cellular ion pumps eventually fail, with accumulation of sodium, chloride, water, and calcium intracellularly (cytotoxic edema), and excitatory amino acid neurotransmitters in the brain, such as glutamate and aspartate, extracellularly. Neonates appear to be more susceptible to glutamate-mediated excitotoxicity than adults. Glutamate injection into specific regions of the brain results in neuronal injury identical to that seen after hypoxia-ischemia, and glutamate antagonists can prevent cell death from anoxia. At high extracellular concentrations, glutamate acts as a neurotoxin and mediates opening of ion channels that permit sodium to enter cells, followed by an influx of chloride ions and water, resulting in osmotic lysis and immediate neuronal death.[29,30] Glutamate also mediates delayed cell death by provoking calcium influx through depolarization-induced opening of calcium channels and by direct stimulation

of *N*-methyl-D-aspartate (NMDA) receptors that open additional calcium channels.[29,30] High intracellular levels of free calcium result in activation of lytic enzyme systems that attack the structural integrity of the cell, generation of free radicals, and impairment of mitochondrial function, resulting in delayed neuronal death. Because of the important role of calcium in regulation of cellular function, drugs such as NMDA and calcium antagonists that prevent calcium influx into damaged cells are being investigated to help reduce delayed ischemic brain injury.

Oxygen free radicals are generated during the reperfusion phase of hypoxic-ischemic injury. It is thought that these radicals contribute to brain injury by their ability to induce free fatty acid peroxidation.[31] The physical integrity of the circulation is often severely compromised after a period of ischemia. It is suspected that oxygen-derived free radicals are at least partially responsible for the increased capillary permeability, edema formation, and tissue damage that commonly follows the restoration of blood flow to ischemic tissues.[32] Severe asphyxial insults tend to produce widespread neuronal necrosis, whereas milder episodes are more likely to induce apoptosis. The latter is an active but noninflammatory response characterized by cell shrinkage, nuclear pyknosis, chromatin condensation, and genomic fragmentation.

16.2.2 Potential Postnatal Sequelae of Birth Asphyxia

The consequences of an episode of asphyxia can be far-reaching and profound. Many organ systems can be adversely affected and contribute to the commonly observed clinical signs of weakness and depression in the neonate. Management can be difficult and complex, but with good supportive care, dramatic recoveries can be made in even severely affected individuals. Unfortunately, it is virtually impossible at the onset of treatment to predict either the severity of injury or the prognosis. Chronic asphyxia in premature individuals or those with sepsis carries the poorest prognosis for intact neurologic survival.

Clinical signs related to the asphyxial injury may not appear until hours or days after the insult. Blood volume abnormalities, such as severe hypovolemia, occurring at delivery may not be obvious until several hours later. Blood pressure may actually be normal at first because capillary capacitance beds are constricted by substances such as catecholamines and angiotensin II. Then as the peripartum stresses decrease over time, circulating hormone levels fall and progressive hypotension and acidosis often develop.[23]

Table 16-2 lists specific clinical conditions and organ system derangements that have been associated with asphyxial injury. Table 16-3 presents therapies for specific organ system dysfunction.

16.2.2.1 CENTRAL NERVOUS SYSTEM

Numerous terms are used in the literature to label foals with hypoxic ischemic brain injury. The term *hypoxic-ischemic encephalopathy* is preferred by some, but other terms include *neonatal maladjustment syndrome; dummy, barker,* or *wanderer foals;* and *perinatal asphyxia syndrome*. Risk factors for asphyxial injury are numerous and include placental insufficiency, placentitis, premature placental separation, maternal illness, umbilical cord diseases (e.g., torsion, funisitis, thrombosis), exogenous induction of labor, dystocia, caesarean section,[33] and a range of postnatal causes including airway obstruction and hemorrhage. Mild asphyxia produces transient tissue ischemia with potentially reversible damage. Prolonged ischemia results in disruption of tight junctions in the capillary endothelium and leakage of osmotic agents and fluid into surrounding brain interstitium, causing vasogenic edema.[34] Brain necrosis occurs and is accompanied by increased intracranial

pressure, progressive brain swelling, reduced cerebral blood flow, and exacerbation of existing ischemia. In critically ill foals, cerebral edema has been associated with cerebellar herniation.[35]

Additional brain injury occurs as a result of repeated seizures, which are common during severe encephalopathy. Repeated seizures cause brain injury through (1) hypoventilation and apnea resulting in hypoxemia and hypercapnia, (2) elevation in arterial blood pressure and cerebral blood flow, (3) progressive neuronal injury because of excessive release of excitatory amino acids such as glutamate, and (4) depletion of the brain's limited energy stores to support seizure activity.

Neonatal foals suffering from HIE display a wide spectrum of neurologic signs that are mostly related to cerebral dysfunction. These include jitteriness, hyperalertness, stupor, somnolence, obtundation, lethargy, hypotonia, clonic seizures, extensor rigidity, hypertonia, subtle seizures, tonic posturing, coma, death, aimless wandering, head pressing, loss of affinity for the dam, inability to find the udder, abnormal vocalization (barking, high-pitched cry), loss of suckle, dysphagia, decreased tongue tone, odontoprisis, blindness, anisocoria, mydriasis, nystagmus, eye deviation, head tilt, head and neck turn, irregular respiration, apnea, abnormally slow respiratory rate, proprioceptive deficits, and spastic dysmetric gait. Blindness is a relatively common complication of perinatal asphyxia and postnatal anoxia from seizure activity and results in extensive gray and white matter injury affecting optic radiations and the visual cortex.[36] In a smaller number of affected foals there may be signs of brainstem or spinal cord involvement. Foals with HIE exhibit a variety of seizure-like activities. Seizures can vary in clinical severity from subtle, which may not be recognized as seizure activity, to generalized and severe (see Seizures, Chapter 19). Jitteriness is associated with mild hypoxia and is not a true seizure but a movement disorder consisting of tremors that can be stopped by gentle restraint. Subtle seizures are called *motor automatisms* and are characterized by paroxysmal events including eye blinking, eye deviation, nystagmus, pedaling movements, a variety of oral-buccal-lingual movements such as intermittent tongue protrusion (so-called “chewing gum fits”), sucking behavior, purposeless thrashing, and other vasomotor changes such as apnea, abnormal breathing patterns, and changes in heart rate. Tonic posturing is another subtle seizure activity characterized by symmetric limb hyperextension or flexion and may be accompanied by abnormal eye movements and apnea. Clonic seizures are true epileptiform seizures with a distinct electroencephalogram (EEG) signature and are characterized by rigid jerky motions that cannot be suppressed by restraint.

Table 16-2 Clinicopathologic Conditions Associated with Peripartum Asphyxia[74]

Organ or System Affected	Clinical Signs	Laboratory Findings	Pathologic Lesions
Central nervous system (CNS)	Hypotonia, hypertonia, seizures, coma, loss of suckle, proprioceptive deficits, apnea	Increased intracranial pressure, increased blood-brain barrier permeability and albumin quotient	CNS hemorrhage, edema, ischemic necrosis
Renal	Oliguria, anuria, generalized edema	Azotemia, hyponatremia, hypochloremia, abnormal urinalysis	Tubular necrosis
Gastrointestinal	Colic, ileus, abdominal distention, bloody diarrhea, gastric reflux	Occult blood (+) feces and reflux, pneumatosis intestinalis	Ischemic mucosal necrosis, enterocolitis, ulceration
Respiratory	Respiratory distress, tachypnea, dyspnea, rib retractions	Hypoxemia, hypercapnia, respiratory acidosis	Hyaline membrane disease, atelectasis, meconium aspiration, pulmonary hypertension
Cardiac	Arrhythmia, weak pulses, tachycardia, edema, hypotension	Hypoxemia, elevated myocardial enzymes	Myocardial infarcts, valvular insufficiency, persistent fetal circulation
Hepatic	Icterus, abnormal mentation	Hyperbilirubinemia, elevated liver enzymes	Hepatocellular necrosis, biliary stasis
Endocrine: adrenals, parathyroids	Weakness, apnea, seizures	Hypocortisolemia, hypocalcemia	Necrosis, hemorrhage

Table 16-3 Drugs Used to Treat Foals with Peripartum Asphyxia[74]

Organ System	Clinical Sign	Drug Therapy
CNS	Seizures	Diazepam: 0.11-0.44 mg/kg IV
		Phenobarbital: 2-10 mg/kg IV q12h; give slowly, monitor serum levels
		Pentobarbital: 2-10 mg/kg IV
	CNS edema	DMSO: 0.5-1 g/kg IV as 20% solution over 1 hr; can repeat q12h
		Mannitol: 0.25-1 g/kg IV as 20% solution over 15-20 min; q12-24h
	Antioxidants	*N*-acetylcysteine: 70 mg/kg IV as 10% solution; q6h
		Vitamin E: 20 IU/kg SC sid
		Thiamine: 10 mg/kg added to IV fluids sid
	NMDAantagonist	Magnesium sulfate: 0.05 mg/kg/h loading dose and then 0.025 mg/kg/hr as IV infusion
Renal	Oliguria, anuria	Dopamine infusion: 2-10 µg/kg/min; monitor blood pressure and pulse
		Furosemide infusion: 0.25-2 µg/kg/hr or 0.25-0.5 mg/kg IV q1-6h; monitor serum electrolytes and hydration status
		Mannitol: 0.5-1 g/kg IV as 20% solution over 15-20 min.
		Dobutamine infusion: 2-15 µg/kg/min; use if cardiac dysfunction is contributing to hypotension and poor renal perfusion
		Fenoldopam: 0.04 µg/kg/min
Gastrointestinal	Ileus, GI distention	Erythromycin: 1-2 mg/kg PO q6h; 1-2 mg/kg/hr as IV infusion q6h
		Cisapride: 10 mg PO q6-8h
		Metoclopramide: 0.25-0.5 mg/kg/hr infusion q6-8h
	Ulcers	Sucralfate: 20-40 mg/kg PO q6h

Not all neurologic abnormalities in large animal neonates are the result of peripartum asphyxia. Other causes of neonatal neurologic disease include the following:

- Metabolic disorders: hypocalcemia, hypomagnesemia, hyponatremia, hypernatremia, hyperosmolality (e.g., hyperlipidemia, hyperglycemia), severe azotemia, hepatoencephalopathy
- Infectious conditions: septic meningitis, septicemia or endotoxemia, equine herpesvirus 1 (EHV-1) infection
- Malformation: hydrocephalus, agenesis of the corpus callosum, vertebral and spinal cord malformations, cerebellar abiotrophy, occipitoatlantoaxial malformation
- Cranial or vertebral trauma
- Toxins

The diagnosis of HIE is unfortunately often done by exclusion. In foals in which there is a clear history of an asphyxial insult, such as dystocia or prolonged stage 2 labor, or that were delivered through cesarean section, the accuracy of the diagnosis should be extremely high. In foals with signs of neurologic disease when there has been no obvious asphyxial insult and when other known causes of brain dysfunction have been ruled out, a diagnosis of HIE should be made with some degree of skepticism. It has been suggested that the term *neonatal encephalopathy* may be more appropriate than HIE for such foals, as the cause may be unclear.

An important but uncommon cause of neurologic signs in neonatal foals is bacterial meningitis. A normal leukogram or the absence of severe leukopenia, neutropenia, and toxic neutrophil changes help rule out septic conditions. A cerebrospinal fluid (CSF) tap is indicated to rule out meningitis in foals in which signs of infection coexist with neurologic signs. Septic meningitis produces an increased nucleated cell count, protein concentration, and IgG index in the CSF. Hypoxic brain damage may result in an increased albumin quotient in the CSF compatible with increased blood-brain barrier permeability. It is also important to remember that foals with postasphyxial encephalopathy are susceptible to infection and that the two conditions often coexist without bacterial involvement of the CNS. The differentiation between HIE and congenital brain anomalies can be very difficult. The most common anomalies include hydrocephalus and hydranencephaly and are

presumptively diagnosed on the basis of persistence of neurologic abnormities or definitively through computed tomography (CT) or magnetic resonance imaging (MRI). Normal serum chemistries help rule out metabolic disturbances.

Currently, suggested treatment of CNS dysfunction in asphyxiated large animal neonates includes seizure control, nursing care to prevent self-trauma, and judicious fluid therapy to avoid overhydration and hypoglycemia or hyperglycemia. Maintenance of effective perfusion and oxygen delivery is the central component of management. Diazepam is used initially to control seizures because of its rapid onset of action. Phenobarbital is used to control severe or repeated seizures. Foals receiving high doses of anticonvulsants should have their vital signs monitored closely because the combination of diazepam and phenobarbital can produce respiratory depression, loss of thermoregulatory control, and hypotension.

A large number of additional therapies are used in the management of foals with suspected postasphyxial brain injury. These therapies are used in the absence of efficacy data and may add little to the principles of therapy described previously. Interstitial cerebral edema is a pathologic feature in a small number of foals. Intravenous dimethyl sulfoxide (DMSO; 0.5 to 1 g/kg of a 10% to 20% solution, slowly over 1 to 2 hours) has been advocated for its ability to reduce brain swelling, intracranial pressure, and inflammation and to act as a diuretic.[22] The osmotic agent mannitol has also been used to reduce cerebral edema and to act as a free radical scavenger. These drugs likely exert little benefit in the control of intracellular edema. To prevent exacerbation of cerebral edema, fluid therapy should be conservative, and sudden changes in osmolality should be avoided. Controversy surrounds the benefits of glucose administration. Hyperglycemia immediately after prolonged hypoxic ischemic injury has been associated with severe neonatal brain injury.[37] Other studies suggest that glucose administration after global hypoxic injury may offer neuroprotection by stimulating insulin release and by reducing glycolysis, free radical formation, and glutamine-mediated injury.[38] Therefore the safest recommendation is to maintain serum glucose concentration within a normal range. *N*-acetylcysteine is a potent antioxidant and antiinflammatory agent that has also been shown to be of benefit in experimental models of neonatal brain injury.[39] A dose rate of 70 mg/kg (as a 10% solution) IV every 6 hours has been suggested in affected neonatal foals. Thiamine is a required cofactor for several important mitochondrial enzymes involved with neuronal metabolism and can attenuate oxygen free radical damage in experimental ischemic brain damage.[40] Thiamine (10 mg/kg sid) is commonly used in foal practice but again in the absence of efficacy data. Other vitamin treatments used by some include vitamin E and vitamin C.

Magnesium sulphate infusion is yet another therapy used to attenuate postasphyxial brain injury in foals. Magnesium is recognized as an inhibitor of NMDA receptor—mediated calcium entry into cells and a membrane stabilizer preventing the persistent membrane depolarization that occurs as a consequence to disruption of the Na/K ATPase pump.[41] Experimental and clinical data regarding the use of magnesium sulphate are conflicting. A recent report not only failed to demonstrate any neurologic benefit of magnesium in postasphyxiated human neonates, but raised the possibility that the therapy could have unexpected cardiovascular and neuromuscular complications.[41] As with many of these agents, any potential effect may be realized only if the treatment is administered before or immediately after the insult.

16.2.2.2

CARDIOPULMONARY EFFECTS

The response of pulmonary vasculature to hypoxia and acidemia includes increased pulmonary vascular resistance, pulmonary hypertension, increased atrial pressure, and persistent right-to-left flow of blood across fetal pathways (e.g., patent ductus arteriosus, foramen ovale). The neonatal pulmonary circulation reflexively

constricts in response to hypoxemia and acidosis.[42] This pulmonary vasoconstriction results in increased pulmonary vascular resistance, pulmonary hypertension, and increased right atrial pressure. If pulmonary arterial pressure exceeds systemic pressure, right-to-left blood flow may result in the reestablishment of fetal circulation (right-to-left flow through the ductus arteriosus and foramen ovale). Persistent fetal circulation (PFC) is associated with severe hypoxemia unresponsive to oxygen therapy owing to severe right-to-left shunting of unoxygenated blood away from the lungs.

When PFC patterns exist, hypoxemia is exacerbated. During asphyxia-induced pulmonary vasoconstriction, substrate delivery to the pneumocytes is impaired and surfactant production decreases with secondary pulmonary atelectasis. Perinatal asphyxia may adversely affect the respiratory control centers of the brain and result in hypoventilation (increased carbon dioxide), secondary to periods of apnea or abnormal breathing patterns.

Adequate surfactant production is dependent on adequate function of the type II pneumocytes and the ongoing delivery of lipid precursors by the blood. If pulmonary blood flow is compromised, surfactant production may stop, and a secondary surfactant deficiency may result.[23,43] The altered permeability characteristics of the lung that have been associated with asphyxial injury also interfere with the function of surfactant, predisposing to atelectasis.[44]

If asphyxia induces in utero passage of meconium, then the fetus may aspirate meconium. Meconium can cause mechanical obstruction of airways, resulting in suffocation or regional lung atelectasis. Partial obstruction produces a ball-valve phenomenon with distal air trapping, ventilation-perfusion mismatching, alveolar overdistention and possible rupture, interstitial emphysema, and pneumothorax.[45] Meconium also induces chemical pneumonitis accompanied by alveolar collapse and edema.[46] The free fatty acids in meconium displace surfactant, resulting in additional atelectasis and decreased lung compliance.[47] See Chapter 19, Respiratory Distress, for further information. Adverse effects of asphyxia on myocardial function include reduced myocardial contractility, left ventricular dysfunction, tricuspid valve insufficiency, and cardiac failure. As a result of cardiac insufficiency the foal may develop systemic hypotension, further impairment of renal blood flow, and decreased pulmonary perfusion. In the human infant, perinatal asphyxia has been associated with myocardial and papillary muscle ischemia and infarction, with decreased myocardial contractility, tricuspid valve insufficiency, and congestive heart failure often resulting. Cardiac isoenzymes may be increased. Treatment is directed at correcting hypoxemia, acidosis, and hypoglycemia and maintaining cardiac output and blood pressure. Inotropic drugs, such as dopamine and dobutamine, are commonly used.

If pulmonary hypertension develops, thoracic radiographs show diminished vascular markings as a result of pulmonary hypoperfusion. Surfactant dysfunction produces diffuse lung atelectasis and a diffuse reticulogranular parenchymal pattern with air bronchograms. Meconium aspiration may produce perihilar infiltrated and focal atelectasis. Echocardiography helps identify arrhythmias.

Support of the respiratory system involves maintenance of oxygenation and ventilation of the patient. Mild to moderate hypoxemia can be treated by increasing the amount of time the foal spends in sternal recumbency or standing and by administering modest flows of humidified intranasal oxygen (2 to 8 L/min [LPM]). Foals with severe hypoxemia and hypercapnia (Pa_{O_2} <40 mm Hg; Pa_{CO_2} <65 mm Hg) require positive pressure ventilation. Respiratory stimulants are used to treat periodic apnea and abnormally slow breathing patterns associated central depression of the respiratory center. Caffeine is used most frequently to stimulate the respiratory neuronal activity and increase receptor responsiveness to elevated carbon dioxide concentrations. Overdosing with respiratory stimulants leads to excessive CNS, myocardial, and GI stimulation resulting in

agitation, seizures, tachycardia, hypertension, colic, and diarrhea. Caffeine is the safest of the methylxanthines to use.

16.2.2.3

RENAL EFFECTS

During asphyxia, redistribution of blood flow away from the kidneys frequently results in decreased renal perfusion and acute tubular necrosis. The renal effects of asphyxia in foals are likely underreported, as overt signs of failure are rare. Transient changes in urine output are often overlooked, particularly when the foals are on fluid therapy. In human infants, oliguria (<1 mL of urine per kilogram of body weight per hour) is the most common clinical sign of acute renal failure; it has also been observed in asphyxiated foals.[22,23] Other signs of renal ischemic damage include peripheral edema, elevated concentrations of serum creatinine and urine γ-glutamyltransferase (GGT), and electrolyte disturbances such as hypocalcemia, hyponatremia, and hypochloremia resulting from renal tubular damage. The oliguric animal should be identified by careful monitoring of fluid intake and output to avoid fluid overload and edema formation. Based on studies in other neonates, renal blood flow and urine output may be increased by the use of low to moderate doses of dopamine (2 to 10 μg/kg/min infusion) or dobutamine (2 to 10 μg/kg/min infusion). Higher doses of dopamine are contraindicated to avoid peripheral vasoconstriction and a decrease in renal blood flow.[22] Therefore, blood pressure and urine output should be carefully monitored during infusion of these substances. The dopamine-1 receptor agonist, fenoldopam, when administered at a low dose (0.04 μg/kg/min infusion) has no effect on system hemodynamics but did cause an increase in urine output in healthy neonatal foals.[48] Diuretics, such as furosemide (0.5 to 2.5 mg/kg/hr as an infusion, or 1 mg/kg intramuscularly [IM] or intravenously [IV] q12h) and mannitol (0.25 to 1 g/kg as 20% solution, infused slowly IV over 1 to 2 hours), have also been successfully used to improve urine output in asphyxiated foals.[22]

16.2.2.4

GASTROINTESTINAL EFFECTS

Hypoxia results in reduced mesenteric and splanchnic blood flow and varying degrees of intestinal ischemia. The most severe form of intestinal dysfunction is NEC. (See the discussion of abdominal distension in Chapter 19.) During GI ischemia, mucosal cell metabolism diminishes and production of the protective mucous layer ceases, allowing proteolytic enzymes to begin autodigestion of the mucosal barrier. Bacteria within the lumen can then colonize, multiply, and invade the bowel wall. Intramural gas is produced by certain species of bacteria, and pneumatosis intestinalis develops. Possible complications include intestinal rupture, pneumoperitoneum, severe bacterial peritonitis, and septicemia.[49] Reflux and feces may be positive for blood. 257
Generalized sepsis often accompanies NEC. As a result of varying degrees of intestinal dysmotility, some 258
foals develop intussusceptions that can be imaged with ultrasound.

Many asphyxiated foals demonstrate mild signs of GI malfunction, including meconium impactions and intolerance to enteral feeding (delayed gastric emptying, abdominal distension, diarrhea, and colic). Colic, bloody diarrhea, and sudden death have been observed secondary to extensive intestinal mucosal sloughing in severe cases. Ileus associated with hypoxic gut damage can result in bowel distention and colic. Nasogastric decompression relieves proximal gut distention. Enema administration stimulates distal colonic function and encourages passage of gas. Metoclopramide and erythromycin may improve gastric emptying and upper GI function. Metoclopramide infusion (0.25 to 0.3 mg/kg infusion, qid) has been suggested to improve gastric emptying and improve small intestinal motility.[22] Cisapride and erythromycin have been used to stimulate small and large intestinal motility. Be certain to allow adequate time for healing of damaged bowel before using prokinetics in a compromised foal. Sonographic examination of the abdomen helps rule out the presence

of intussusceptions and other obstructive lesions before motility modifiers are administered. Severe large bowel distention may require percutaneous trocarization. Alternatively, exploratory celiotomy may be performed, but the multisystemic derangements often make such animals poor surgical risks.

To reduce the risk of NEC, asphyxiated foals should have enteral feeding reduced or withheld until intestinal motility has returned. Reassuring signs include manure passage, normal borborygmi, and stable vital signs (temperature, blood pressure). Enteral feeding should be started cautiously with fresh mare's milk or colostrum. Foals with severe GI dysfunction should have enteral feeds withheld and should be started on parenteral nutrition. Because intestinal ischemia may predispose to ulceration, histamine-2 (H_2) blockers (cimetidine, ranitidine), proton pump inhibitors (omeprazole), or cytoprotective agents (sucralfate) are recommended.

16.2.2.5 HEPATIC AND ENDOCRINE FUNCTION

Hypoxic liver damage produces an increase in hepatocellular and biliary enzymes. Affected neonates are usually icteric. Impaired hepatic function renders the neonate more susceptible to alteration in glucose homeostasis and can result in decreased hepatic defense mechanisms and increased susceptibility to sepsis. Endocrine organ damage associated with hypoxia includes adrenal gland hemorrhage and necrosis with hypocortisolemia. Parathyroid damage may result in hypocalcemia. Pancreatic injury and abnormal insulin activity can occur.

16.2.2.6 IMMUNE DYSFUNCTION

Maladjusted foals are at increased risk for FPT because of their abnormal nursing behavior. Serum IgG levels should be evaluated, and colostrum and/or plasma administered to treat FPT.

16.2.3 Supportive Care and Prognosis of the Acutely Asphyxiated Foal

A summary of therapies for specific organ dysfunction associated with peripartum asphyxia is presented in Table 16-3. Blood glucose, blood gases, and fluid and acid-base balance should be monitored closely. In severely affected animals, both arterial and central venous pressures are monitored. Nursing care must be carefully performed to avoid secondary infection.

Prognosis varies with the severity and duration of clinical signs. In one intensive care unit, 70% of asphyxiated foals recover, with most making a complete recovery. A poor prognosis was associated with foals that failed to show any signs of improving neurologic function in the first 5 days after delivery; foals that remained comatose or experienced severe, recurrent seizures; and foals that developed septicemia.[22]

16.3 RESUSCITATION OF THE NEONATE

John K. House

Assisted deliveries are usually associated with moderate to severe fetal stress. Survival of the compromised fetus is facilitated by prompt initiation of supportive care. Prior preparation of a “crash box” or “crash cart” (Fig. 16-1) expedites location of the necessary supplies and equipment. Passage and subsequently aspiration of meconium often accompany fetal stress. Suction, if available, is useful for clearing the airway but should be used judiciously as prolonged pharyngeal and tracheal aspiration induces vagally mediated bradycardia.[50] Vigorously rubbing the

skin over the legs stimulates a somatic-respiratory reflex and may help initiate respiratory effort.[51] Thermoregulation is important, as recovery from acidosis is delayed by hypothermia.[52] Cold stress leads to increased metabolic needs and produces hypoxia, hypercarbia, metabolic acidosis, and potentially hypoglycemia—metabolic sequelae that resuscitation is aimed at correcting.[53] Weak fetuses are often born with strongly beating hearts but have difficulty initiating adequate inspiratory efforts to expand their lungs. Positive pressure ventilation is required to overcome surface tension in alveoli and the elastic recoil of lung tissue. Fluid within alveolar spaces and the lumen of the tracheobronchial tree is absorbed into the pulmonary interstitium most efficiently at thoracic pressures between 35 and 40 cm H_2O.[5] Less pressure is usually needed for succeeding breaths. Intrathoracic pressure that exceeds 40 cm H_2O increases the risk of damaging the alveolar epithelium. Observation of chest wall movement is a more reliable sign of appropriate inflation pressures than pressure readings from a manometer. Nasal insufflation with oxygen does not facilitate resorption of lung fluid and is largely ineffective.

If an endotracheal tube and a laryngoscope are available the fetus should be intubated. Placing a rigid stylet in the endotracheal tube and positioning the neonate in sternal recumbency with head and neck extended makes intubation easier. Calves may also be intubated blindly via palpation of the larynx. Ventilation of asphyxiated newborn neonates with 100% oxygen is usually recommended, but experimental work with newborn pigs and a study in humans suggest room air may be as effective.[54,55] Ventilation with a pulmonary resuscitation bag (Ambu bag) with a pressure relief valve set at 42 cm H_2O avoids inadvertent overinflation.[56] If a laryngoscope and an endotracheal tube are not available, positive pressure ventilation can be achieved using an esophageal feeding tube. The tube is passed into the esophagus with the fetus in right lateral recumbency. The distal end of the tube is located approximately one third of the distance “down” the neck. The esophagus is compressed distal to the end of the tube, with one hand taking care not to trap the trachea, and the muzzle is gripped with the other hand to seal the nares. The operator then blows into the tube and, providing the esophageal and muzzle seals are good, air is delivered into the lungs.[57] Direct mouth-to-mouth resuscitation is unhygienic and delivers air mainly into the abomasum. Respiratory stimulant (analeptic) drugs, such as doxapram hydrochloride, may be used to stimulate respiration in neonates but should be used judiciously, as the stimulatory action of the drug is nonselective. Convulsions may be observed with repeated administration, increasing the demand for O_2 in an already hypoxic neonate.[58] Analeptics should not be used as a substitute for ventilatory support.

Fig. 16-1 Supplies for a “crash box.”

Ambu bag
Oxygen mask
Oxygen cylinder, regulator, and pressure relief valve
Nasal insufflation tubing
Endotracheal tubes
Laryngoscope
KY jelly
Brown gauze, umbilical tape, and adhesive tape
Razor
IV catheters, T-ports, PRNs, and suture
J wire
Needles and syringes
Emergency surgery pack, scalpel blades and surgical gauze
Fluids (saline, lactated Ringer's, and dextrose), administration and extension sets
Blood collection tubes and needles
Drugs (epinephrine, lidocaine, prednisolone, doxapram, sodium bicarbonate, calcium chloride, and dopamine) (observe necessary storage requirements)

Progressive hypoxia and tissue acidosis lead to bradycardia, decreased cardiac contractility, and eventually cardiac arrest. If apnea progresses to cardiopulmonary arrest, artificial circulation in the form of cardiac massage needs to be provided, along with positive pressure ventilation. Cardiac massage in lambs and kids is performed by compressing the ventral thorax behind the elbows between the thumb and two fore fingers. Cardiac compressions in calves is achieved by placing the patient in lateral recumbency and compressing the ventral thorax behind the elbows against a sandbag placed under the calf in a position opposite the resuscitator's hands. Effectiveness of cardiac compressions may be monitored by checking for a palpable pulse and by observing changes in mucous membrane color. When available, an electrocardiograph is useful to monitor the electrical activity of the heart. Abdominal wrapping is used in human and small animal medicine during cardiopulmonary resuscitation to improve myocardial perfusion by returning pooled venous blood from the abdomen and limbs to the central compartment and by reducing the runoff of arterial blood to the caudal periphery.[59] Treatment with epinephrine is recommended for asystole or if the heart rate stays below 60 beats/minute. Epinephrine increases systemic vascular resistance, redistributing circulation away from the periphery to the cerebral and myocardial circulation, and increases myocardial contractility, heart rate, and cardiac output. Epinephrine is initially administered at a dose of 0.02 mg/kg either intravenously or intratracheally (via the endotracheal tube). There are reports of cases in the human literature in which there was no response to this dose but responses were observed to doses as high as 0.2 mg/kg.[60] High-dose epinephrine therapy may increase the risk of acute renal failure and intracranial hemorrhage and is not recommended as a primary treatment.[53] Peak plasma concentrations of epinephrine are achieved 60 seconds after

endotracheal administration. Plasma concentrations of epinephrine after endotracheal administration are approximately 10 times lower than those achieved with intravenous administration, so intravenous access should be established as soon as possible.[61] Administration of large doses of epinephrine endotracheally to compensate for the reduced absorption is associated with prolonged hypertension and is not recommended.[62] In an emergency the endotracheal route of drug administration may be used for other lipid-soluble drugs such as lidocaine or atropine but should not be used for non—lipid-soluble drugs.[63] When drugs are administered by the endotracheal route, they should be instilled as deeply as possible into the tracheobronchial tree using a catheter inserted beyond the tip of the endotracheal tube.[64] Dilution of the drug in 1 to 2 mL of saline may aid drug delivery. Rapid intravenous infusion of warm isotonic fluid (lactated Ringers 20 to 40 mL/kg) increases the circulating fluid volume and may help to compensate for the increased vascular volume. The use of sodium bicarbonate, atropine, and calcium chloride in cardiopulmonary resuscitation of neonates is controversial. A basic protocol for resuscitation of the newborn is presented in Fig. 16-2.

259

260

Fig. 16-2 Resuscitation of the neonate.

The rationale for sodium bicarbonate administration in the presence of lactic acidosis is to increase extracellular pH and thereby improve cardiac function, perfusion and oxygenation of peripheral tissues, intracellular pH, and lactate metabolism.[65] Sodium bicarbonate administration is associated with production of carbon dioxide; correction of the acidosis requires removal of the CO_2, which is dependent on adequate ventilation and pulmonary blood flow. If pulmonary ventilation or pulmonary blood flow is inadequate, administration of sodium bicarbonate will result in hypercarbia. Excessive administration of sodium bicarbonate causes alkalemia and a right shift in the oxygen-hemoglobin dissociation curve, reducing oxygen availability to tissues. Paradoxic CNS acidosis has been documented in association with bicarbonate administration during cardiopulmonary resuscitation,[66] and acute intracellular potassium shifts secondary to sodium bicarbonate therapy may be associated with an increased incidence of cardiac arrhythmias.[67] Administration of sodium bicarbonate is recommended only if adequate ventilation has been established and when all other measures have not been successful.[68] The dose is 1 to 2 mEq/kg administered by slow intravenous injection. Because catecholamines are inactivated by bicarbonate and because calcium will precipitate when mixed with bicarbonate, intravenous catheters should be flushed between infusions of drugs.[64]

Use of atropine in resuscitation is based on its peripheral effects as a competitive antagonist of acetylcholine, reducing vagal tone and increasing conduction through the atrioventricular node. The effect of atropine is dependent on the degree of vagal stimulation that is causing the bradycardia. Vagal stimulation is not the cause of bradycardia in hypoxic newborns; therefore a response is unlikely. Possible deleterious effects of atropine administered at therapeutic doses are increased myocardial oxygen consumption and precipitation of atrial and ventricular tachyarrhythmias.[69] In low doses atropine stimulates the medullary vagal nuclei, causing paradoxic bradycardia with slowing of atrioventricular conduction.[70]

260
261

The belief that increasing the availability of calcium during cardiac arrest might improve myocardial function led to inclusion of calcium chloride in cardiopulmonary resuscitation protocols. Calcium has been implicated as a cause of postresuscitation cerebral ischemia, as high levels of calcium promote prolonged vasoconstriction, exacerbating cerebral and myocardial hypoperfusion.[71] Currently administration of calcium chloride is recommended only in cases of known hypocalcemia and hyperkalemia.

16.3.1 Postresuscitation Care

After resuscitation it is important to closely monitor cardiopulmonary function. Steroids have been recommended to reduce postischemic cerebral edema via preservation of membrane integrity, inhibition of prostaglandin and free radical formation, lysosomal membrane stabilization, and preservation of vascular membrane permeability, but there is no documented evidence demonstrating their effectiveness.[72] The β_1-agonist dopamine may be administered via a continuous slow intravenous infusion (2 to 10 µg/kg/min) if peripheral perfusion is poor, as indicated by decreased capillary refill, absent or decreased pulses, cool extremities, tachycardia, and oliguria. Infiltration of dopamine into tissues can produce local tissue necrosis. Dopamine, like epinephrine, is inactivated in alkaline solutions and should not be administered in sodium bicarbonate.[64] Serum electrolytes, blood gases, and blood glucose should be periodically monitored if laboratory support is available, and appropriate fluid therapy administered to correct deficits. Positioning the newborn in sternal recumbency and provision of oxygen via nasal insufflation helps the compromised neonate maintain blood oxygen saturation. Body temperature should be monitored closely, and heating lights and pads provided. During the course of the first 24 hours of life the newborn should receive approximately 15% of its body weight in colostrum. If the coordination of the newborn is questionable, colostrum should be tube-fed to avoid

aspiration. Immunoglobulins are often absorbed poorly by the compromised neonate, so passive transfer should be evaluated at 18 hours of age and plasma administered if the plasma immunoglobulin concentration is less than 400 mg/dL.

17 Chapter 17 Initial Management and Physical Examination of the Neonate

Guy D. Lester

John K. House

Wendy E. Vaala

17.1 APPROACH TO THE HIGH-RISK OR COMPROMISED NEONATAL FOAL

WENDY E. VAALA

The abnormal large animal neonate often presents diagnostic and management challenges to the veterinarian. Familiarity with neonatal characteristics and behavior, as well as with neonatal disease processes, is critical for a successful outcome. Despite dramatic advances in neonatal intensive care, many foals still die, not because their primary problem is untreatable, but because veterinary intervention was delayed, delivery was unattended, neonatal compromise was not recognized in a timely fashion, or critical care was unavailable or not economically feasible (Box 17-1). It is absolutely essential to recognize abnormalities *early* in the course of the disease process. Large animal neonates are born with few nutritional, physiologic, or immunologic reserves. Any condition that prevents them from standing and nursing soon after birth represents a potentially fatal condition. Unfortunately, signs of illness in the neonate are frequently vague and nonlocalizing. Many high-risk newborn animals look relatively good during the first hours after birth. This “grace period” is often followed in 12 to 24 hours by a worsening of condition because of the specific disease process itself as well as disruption of normal adaptive processes. The presence of one localizing sign such as diarrhea may obscure the fact that other organ systems are involved as well. Multiple problems in the same individual seem to be the rule rather than the exception.

Many weak foals begin to fade as a result of a series of problems that need to be systematically addressed. Therefore diagnosis on the basis of physical examination alone is extremely difficult. Prompt collection of a complete database (history, hematologic assessment, clinical chemistries, immunoglobulin status, radiographs, and ultrasonography) is often necessary to form a realistic idea of the neonate's problems and prognosis. The veterinarian must initiate treatment for the specific disease process while addressing the unique metabolic demands and physiologic instability of the newborn.

Another neonatal tendency that is extremely important in dictating the time course of clinical diagnosis, monitoring, and intervention is the rapidity with which changes in condition can occur, either for better or worse. Even a short delay in institution of therapy can make the difference between success and failure. The placentation of the large animal fetus does not allow transfer of immunoglobulins from mother to fetus in utero, and the newborn is dependent on the ingestion of colostrum shortly after birth for the majority of its immunoglobulins. Even with a normal level of circulating immunoglobulin, the immune system of the neonate is not as effective as that of the adult, and if failure of passive transfer of immunoglobulins occurs (see Chapter 53), the neonate is at higher risk for acquiring severe, generalized infections. A foal should be considered high risk if any of the abnormal periparturient events listed in Box 17-1 have been observed.

17.2 EXAMINATION OF THE POSTPARTUM MARE AND PLACENTA

When accompanying a sick newborn foal, the mare should be evaluated thoroughly, and a complete foaling history should be acquired (see Chapter 15).

If available, the fetal membranes should be weighed and examined for integrity, abnormal thickening, discharges, villous atrophy, and other abnormalities. The placenta should be scrutinized systematically for valuable information about the in utero environment.[1,2] Fetoplacental infection, associated with bacterial, viral, and fungal agents, is one of the most important causes of abortion, stillbirth, and perinatal mortality in the equine species.[3] Normal placental weight for thoroughbreds ranges from 4.5 to 6.4 kg (10 to 14 lb) or about 11% of the foal's body weight[4]; placentas that weigh over 6.4 kg should be considered potentially abnormal (edema or placentitis), and those that weigh less than 4.5 kg may be incomplete or have severe villous atrophy.

Cases of chronic placentitis are usually recognized by thickening and discoloration of the chorion. Because most intrauterine infections begin as an ascending placentitis of the chorioallantois, the area of discoloration and thickening originates at the cervical star and extends up the body of the placenta. Acute cases of placentitis may require histopathologic examination for a diagnosis.[5] If placentitis is suspected, fetal fluids or membranes should be cultured, and sections of amnion and chorioallantois should be saved in formalin for histopathologic examination. Organisms most commonly associated with endometritis may also be associated with placentitis. Pathogens include *Streptococcus zooepidemicus, Leptospira* species, *Escherichia coli*, nocardioform actinomycetes, fungi, *Pseudomonas aeruginosa, Streptococcus equisimilis, Enterobacter agglomerans, Klebsiella pneumoniae,* and alpha-hemolytic *Streptococcus*.[6,7] Diffuse placentitis is associated with hematogenous spread of infection such as seen with *Leptospira* infection. Nocardioform placentitis is characterized by focally extensive placentitis at the base of the placental horns at the junction of the horns and the body of the uterus.[7] The affected placenta is usually covered with thick, tenacious brown exudate. Fungal placentitis often results in a sticky brown mucoid exudate covering parts of the chorion and is often associated with the birth of a small, emaciated foal.[5] Sabouraud's agar should be used to isolate suspected fungal pathogens. A direct smear of the exudate can be examined with Gomori's methenamine silver stain.[6] *Aspergillus* and *Mucor* species are the most common fungal pathogens isolated.[8] Systemic fungal infection of the foal is relatively rare.

262

263

17.2.1

Box 17-1 Periparturient Events Associated with High-Risk Neonates

17.2.1.1

PREPARTUM EVENTS

Premature udder development and/or precocious lactation in the dam

Severe maternal illness

Severe maternal malnutrition

Exposure to endophyte-infected fescue within 2 months of delivery

Inadequate prenatal maternal immunization

Advanced maternal age

17.2.1.2 PARTURIENT EVENTS

- Premature delivery
- Prolonged gestation
- Premature placental separation
- Meconium staining of fetus, placenta, and/or fluids
- Agalactia
- Severe dystocia
- Cesarean section
- Induced delivery
- Grossly abnormal or heavy placenta (>11% of foal's body weight)

17.2.1.3 POSTPARTUM EVENTS

- Failure of neonate to stand and nurse within 3 hours of delivery
- Low Apgar score
- Abnormal physical examination findings including generalized weakness, poor suckle, severe angular limb deformities, enlarged or bleeding umbilicus, patent urachus, respiratory distress, diarrhea, colic, or other signs of localized infection

Pending culture results, the foals from grossly abnormal placentas should be considered at high risk of being infected. Such foals should have a blood culture submitted and their leukogram and creatinine concentration evaluated. Prophylactic treatment with broad-spectrum antibiotics is indicated.

If the chorioallantois is unusually heavy, it may fail to rupture at the cervical star, resulting in premature or abnormal placental separation with the rupture of membranes occurring near the base of one horn. Foals may experience bouts of hypoxia associated with such deliveries. Early postpartum treatment with drugs, such as dimethyl sulfoxide (DMSO) or mannitol, to decrease cerebral edema is indicated at the first signs of neonatal hypoxic ischemic encephalopathy (i.e., dummy foal syndrome).

Adenomatous hyperplasia of the allantois may appear as hyperplasia and hypertrophy of the epithelial cells of the allantois with the formation of intraepithelial glands. More severely affected membranes may have raised firm tan nodules on the allantoic surface of the chorioallantois.[9] These lesions consist of dilated, anastomosing glands surrounded by loose, collagenous stroma. Inflammatory changes are thought to be secondary to the adenomatous dysplasia. The cause of this lesion is not known, but it is seen with chronic placentitis, placental edema, and fetal diarrhea.[6,9] Umbilical cord abnormalities may also affect the fetus.[10] Granular debris and golden meconium particles on the amniotic portion of the cord suggest local inflammation. An excessively long umbilical cord (normal range is 36 to 83 cm) may result in strangulation of the fetus with evidence of edema and vascular occlusion around the head and neck. If there is excessive twisting of the cord, there may be compromised fetal circulation and/or obstruction of the urachus. Urachal obstruction may contribute to urachal patency or bladder rupture. An unusually short cord is prone to premature rupture and hemorrhage and may predispose the foal to hypoxic injury.

The mare's udder, milk, and reproductive tract should be carefully examined. After birth the quality of colostrum may be assessed by visual inspection (thick, sticky) or by colostrometer (specific gravity <1.060 is normal) (see Chapter 53). A full, distended udder usually indicates that the foal is not nursing adequately, but in rare instances it may accompany mastitis. In mares with mastitis the milk may appear normal on visual inspection. A flaccid and empty udder may indicate either an aggressively nursing foal or a mare that is not lactating sufficiently. One way to distinguish the two is to muzzle the foal for 1 to 2 hours and then check the amount of milk in the udder.

The mare's reproductive tract should be evaluated if there is a history of vaginal discharge, retained placenta, or traumatic birth or if the mare appears sick or febrile. The mare's appetite and manure production should be monitored. Postpartum mares are at increased risk for developing gastrointestinal disease. Causes of colic in the postpartum mare include impaction of the large colon or cecum, cecal rupture, large colon displacement, large colon torsion, rectal prolapse with rupture of the mesocolon, ischemic necrosis of the descending colon, diaphragmatic herniation of abdominal viscera into the thorax, rupture of the uterine artery, hematoma formation within the broad ligament or uterine wall, peritonitis secondary to uterine trauma, rupture, or prolapse, and metritis.

Diagnostic aids include a careful history of events surrounding delivery. Prepartum maternal problems such as hydrops or prepubic tendon rupture and ventral abdominal hernia formation predispose to specific problems. Hydrops, if severe, can result in uterine rupture, leading to postpartum peritonitis. Prepubic tendon rupture and rectus abdominis damage can produce intraperitoneal inflammation leading to intraabdominal adhesions, bowel trauma, and peritonitis. A history of dystocia increases suspicions of intrauterine trauma, uterine rupture, metritis, and peritonitis. Dystocias have also been associated with bowel damage including cecal rupture. If the mare experienced rectal prolapse, she is at increased risk for rupture of the mesocolon and secondary disruption of blood supply to the descending colon resulting in intestinal ischemic necrosis and peritonitis. Retained fetal membranes increase the risk of metritis and secondary peritonitis.

It is common practice to feed mares a laxative diet following parturition to reduce the risk of impaction. The mare should be dewormed within 24 hours after delivery to reduce the foal's parasite exposure.

17.3 RESTRAINT OF THE FOAL

The uncooperative nature of many neonatal foals can seriously limit the quality of care provided, and identification of effective restraint techniques often becomes a concern equal in importance to medical therapy. In general, procedures should be performed as quickly and quietly as possible. For minor procedures such as venipuncture, most foals can be successfully restrained in the standing position, with the foal held against a wall or in a corner of

263

264

the stall. One of the restrainer's arms is placed around the foal's chest, and the opposite hand grasps the tail base and holds the tail up over the rump. If foals are held too tightly, they tend to collapse, then leap forward. Alternatively, most foals stand well when both ears are held tightly at the base; this technique also provides excellent access to the jugular vein.

For procedures that are more involved and time-consuming, it is highly recommended that foals less than 2 weeks of age be placed in lateral recumbency. The use of local anesthetic placed with a small needle facilitates catheter placement and arterial blood gas collection. Additional details concerning foal restraint can be found in other texts.[11]

17.4 PHYSICAL EXAMINATION OF FOALS

Guy D. Lester

17.4.1 Physical Appearance and Bodyweight

The degree of physical maturity should be considered in relation to the estimated gestational age. This assessment should be made in light of the variable gestational length in horses. Typically, gestational length is calculated from the time of insemination through birth, which overestimates the true gestational period by as much as 7 days. The mean gestational period in thoroughbreds is approximately 340 to 342 days, with 95% of mares foaling at 327 to 357 days.[12] There are a number of factors that influence this period, including breed, gender, and the time of year. Colts on average have a gestational length that is approximately 1.5 to 2.5 days longer than that of fillies. They also are slightly heavier, are slower to stand, and have a heavier placenta.[13] Mares that develop a pregnancy early in the breeding season have longer pregnancies than those that conceive late in the season. This can affect gestational length by as much as 10 days.[12,14] In some but not all breeds it has been suggested that dam, sire, and dam's sire play a role in determining gestational period.[15] Physical characteristics of immaturity include low birthweight, small body size, short and shiny hair coat, doming of the head, periarticular laxity, and droopy ears. Foals with a shortened gestational period and signs of physical immaturity are termed *premature,* whereas foals that are physically immature in the face of an appropriate gestational length are termed *dysmature*. Foals born after 356 days should be regarded as postterm. Such foals are distinguished from foals that are postmature, a condition of increased morbidity as a consequence of failing placental function.[15] Postmature foals tend to have a lean and lanky physical appearance. Numerous factors influence a foal's body weight at birth including breed, gender, gestational age, and intrauterine environment. Estimates of body weight for newborn thoroughbred foals for the purpose of drug calculation range between 40 and 55 kg, although many healthy foals may well exceed this range.

17.4.2 Foal Behavior

Normal foals achieve sternal recumbency with a raised head within minutes of birth. They also should be highly responsive to a range of tactile, visual, and auditory stimuli within 5 minutes of delivery.[16] Attempts to rise should begin within 30 minutes. Initial attempts may be unsuccessful, but most foals are standing with control by 1 hour of age (mean 57 minutes; range 15 to 165 minutes).[17] Initially the stance is characteristically wide-based, with moderate truncal swaying both forward and backward and from side to side. The suck reflex should be present within minutes of birth and should be vigorous by 30 minutes. After a period of adjustment the normal foal will eventually discover the mare's udder and begin sucking. This is typically achieved before 2 hours (mean 111 minutes; range 35 to 420 minutes); most foals have sucked twice by 2½ hours of age. Sucking periods vary

in duration between 1 and 5 minutes and are interspersed with periods of sleep that last approximately 7 minutes. A foal that spends long periods at the udder may not be getting an adequate intake of milk.

It is important to watch the foal during sucking to confirm appropriate teat contact and swallowing movements. The foal should also be observed after sucking for evidence of nasal regurgitation of milk. The normal neonatal foal spends approximately one third of its life recumbent; this is in contrast to the adult horse, which spends 5% to 10% of a 24-hour period in recumbency. An important part of the physical examination is assessment of the foal's attitude. Normal foals are bright, alert, and very responsive to environmental stimuli. They should be curious and demonstrate frisky play at as early as 2 hours of age. Galloping can be observed by as early as 6 to 7 hours of age. Normal parameters for the foal are listed in Tables 17-1 to 17-3.

Recommendations to clients as to when veterinary intervention should be sought vary from practice to practice. The "1-2-3" rule is often quoted: the foal should be standing by 1 hour after birth, the foal should have sucked by 2 hours, and the placenta should be cleared by 3 hours. Some have translated this into a "2-4-6" rule for clients: seek veterinary attention if the foal has not stood by 2 hours, the foal has not sucked by 4 hours, or the placenta has not been cleared by 6 hours. These recommendations are used only as a rough guide and will obviously be influenced by peripartum conditions and client experience.

264
265

Table 17-1 Normal Physical Examination Parameters of the Neonatal Foal and Calf

Parameter	Foal	Calf
Gestational age	241 days (327-365) <320 days = premature	278-282 (Holstein) 281-282 (Shorthorn) 292 (271-310) Brahma
Time to suckling reflex (stimulated by placing a finger in the mouth)	2-20 min	2-20 min
Time to stand	57 min (15-165 min) <2 hr abnormal	60-158 min 60-228 min without dam
Time to nurse from mother	111 min (35-240 min) <3-4 hr abnormal	104 min
Body temperature	37° C-38° C (99° F-102° F) AM nonstressed value	37° C-38° C (99° F-102° F)
Heart rate	1-5 min postfoaling <60 beats/min 6-60 min postfoaling 80-130 beat/min Day 1-5 80-120 beats/min	90-110 beats/min
Respiratory rate	Postfoaling for 30 min 60-80 breaths/min 1-12 hours in sternal recumbency 30-40 breaths/min

AST (SGOT) (IU/L)	154 ± 55	225 ± 60
LDH (IU/L)	487 ± 100	490 ±100

AST, Aspartate aminotransferase (SGOT); *BUN,* blood urea nitrogen; *GGT,* γ-glutamyltransferase; *LDH,* lactate dehydrogenase; *SDH,* sorbitol dehydrogenase.

A potentially critical consequence to a delay in the onset of feeding is failure of passive transfer of maternal immunoglobulin. Foals should be supplemented with 20 mL/kg of good-quality colostrum by bottle or tube ideally before 6 hours of age. Measurement of serum immunoglobulin G (IgG) should be made between 12 and 18 hours of age. A normal foal that has consumed adequate amounts of colostrum will have a serum IgG measurement substantially greater than 800 mg/dL. Failure of passive transfer is generally defined as a serum IgG less than 400 mg/dL; partial failure of passive transfer is used when the serum IgG is between 400 and 800 mg/dL. Many authors have identified an association between low serum IgG and morbidity and mortality, most commonly caused by sepsis. Tetanus prophylaxis, in the form of antitoxin (1500 IU), should be administered to foals with untreated failure of passive transfer.

A modified Apgar score has been used in foals to semiquantitate the severity of signs that occur in response to peripartum asphyxia (Table 17-4).[18] In human neonatal practice the acronym stands for activity, pulse, grimace,

appearance, and respiration. The modification used in equine practice refers to appearance, pulse, grimace, attitude, and respiration. Appearance refers to oral mucous membrane color; pulse is self-explanatory and uses 60 beats per minute (bpm) as a cutoff; grimace is assessed in response to stimulation of the nasal mucosa, the inside of the pinnae, and the region over the thoracolumbar area adjacent to the spine; attitude reflects the degree of muscle tone; and respiration refers to ventilation rate and rhythm, with 30 breaths per minute as the cutoff. Each category is scored from 0 to 2 points, with a score of 10 being optimal. A score of 0 to 3 indicates marked depression; 4 to 6, moderate depression; and 7 to 8, mild asphyxial injury. Normal foals have a score of 9 or 10. Ideally the modified Apgar calculation should be made within the first minute after birth, but certainly within 15 minutes of delivery. Repeating the score 4 minutes later is recommended. Foals with low scores typically require aggressive resuscitation, whereas mildly affected foals may respond to vigorous rubbing, stimulation of the nasal mucosa, and limb movement.

265

266

Table 17-4 Apgar Score: Assessment of Neonatal Asphyxia[19]

Parameter	0 Points	1 Point	2 Points
APPEARANCE	Gray or blue mucous membranes	Pale pink mucous membranes	Pink mucous membranes
PULSE (beats per minute [bpm])	Absent	<60, irregular	60, regular
GRIMACE			
Nasal stimulation Ear tickle Thoracolumbar stimulus	No response No response No response	Grimace Head and neck motion Head and neck motion	Strong grimace, sneeze Ear tickle, head shake Attempt to stand with head, neck, limb motion
ATTITUDE (muscle tone)	Limp, lateral recumbency	Semisternal, some limb flexion	Sternal
RESPIRATION (breaths per minute)	Absent	<30, irregular	30, regular, can whinny

17.4.3

Maternal Behavior

Any intervention should be made in consideration of the impact it may have on the relationship between the mare and the foal. Maternal behavior toward the foal is instinctive and can be modified or disturbed through excessive veterinary intervention. Maternal recognition is largely dependent on smell, and treatments may alter foal odor, thereby interfering with the normal bonding process. Separation of foal and mare may be unavoidable if necessary treatments are to be provided; however, maintenance of an environment in which the mare has continual access to her foal with respect to sight and smell is ideal. It is important to distinguish refusal to suck from true rejection; the latter commonly involves aggression toward the foal. Mares may be reluctant to allow the foal to suck if they are experiencing pain from udder edema, pelvic or perineal disease, or primary gastrointestinal problems. In addition, uterine contractions associated with passage of the fetal membranes may also cause transient discomfort in the mare. Management is dependent on recognition and treatment of the underlying problem. This may include provision of analgesia, local therapy of the udder (heat therapy, massage), and oxytocin (10 to 15 IU given intramuscularly [IM]) to facilitate milk letdown. Tranquilization with acepromazine may also be helpful.

Maiden mares commonly, and multiparous mares occasionally, demonstrate signs of confusion, fear, and anxiety with the arrival of a newborn foal. This usually results in sudden movement of the hindquarters away from the foal as it attempts to find the udder, mare squealing, and heightened sensitivity. Mares may attempt to bite or kick the foal if they are unable to escape. This is accentuated by placement into a busy or noisy environment, typical of many veterinary practices in spring. The most successful approach to managing anxious mares is through a combination of a low-stress environment, tranquilization, and patience. It is important to avoid threatening verbal or physical punishment, as this only heightens the mare's anxiety. The use of a grazing muzzle or hobbles may be needed to reduce the risk to the foal from kicking or biting.

Risk factors for foal rejection include first birth, a history of previous rejection, disruption to the environment (e.g., forced separation, noise), and breed.[20,21] Rejection may occur more often in Arabian mares and more commonly within certain family lines within the breed.[21]

17.4.4 Body Temperature

Rectal temperature in foals reportedly ranges from 99° F to 102° F (37.2° C to 38.9° C) during the first 4 days after birth.[17] The upper end of the normal range, which is approximately 1° F (0.6° C) above the upper end of the adult range, is strongly influenced by environment and exercise. Temperature can be variable in foals with systemic sepsis; in the early stages of sepsis the rectal temperature is commonly within the normal range or mildly elevated. Foals in septic shock usually have a low rectal temperature, and those with localized infection often are febrile.

17.4.5 Cardiovascular System

Physical assessment of the cardiovascular system includes examination of visible mucous membranes, palpation of peripheral arterial pulses, assessment of extremities for warmth, detection of limb or ventral edema, and cardiac auscultation. In the foal, preferred sites for subjective assessment of pulse rate, regularity, and strength include the dorsal metatarsal artery, the brachial artery, and the carotid artery. The dorsal metatarsal artery is easily palpated in healthy foals on the lateral aspect of the third metatarsal bone. The brachial artery is palpated at the level of the medial collateral ligament of the elbow joint. Reduced pulse pressure can be caused by a range of diseases including systemic sepsis, perinatal asphyxia, and prematurity. Indirect blood pressure monitoring is most commonly performed using an automated oscillometric device with a cuff positioned around the base of the tail or over the dorsal metatarsal artery.[22] These devices reasonably reflect direct pressure measurements when used carefully with several repetitions. There are important limitations of indirect or direct blood pressure measurement in overall assessment of the cardiovascular system. In healthy foals the correlation between arterial blood pressure and cardiac output, one of the best available parameters to assess circulatory function, is acceptable but decreases significantly when there is altered systemic vascular resistance—a circumstance that is likely common to several common diseases. Recent descriptions of noninvasive methods to measure cardiac output, such as volumetric echocardiography, have shown good correlation with more robust but invasive techniques in anesthetized foals. The question remains if this correlation will be sustained in critically ill foals.

266

267

Cardiac auscultation is an important part of the physical examination of the newborn foal. This should include auscultation of both the left and right hemithorax. The heart rate can be highly variable in neonates and is dependent on age. Immediately after delivery the rate is around 60 bpm (range of 40 to 80 bpm), and it increases over the first several hours of life to approximately 120 bpm. This should stabilize to within a range of 80 to 100 bpm during the first week. Increases associated with activity and excitement should be expected. Cardiac

arrhythmias occur commonly during the first hour after birth in apparently healthy neonatal foals; most arrhythmias are restricted to the initial 15 minutes of postpartum life. These include atrial premature contractions, paroxysmal atrial fibrillation, atrioventricular block, ventricular premature contractions, and ventricular tachycardia.[23–25] Most are attributable to hypoxia and high vagal tone. Cardiac arrhythmias after an hour of age should be considered abnormal.

Cardiac murmurs are also commonly auscultated in foals during the early neonatal period. The vast majority are localized to the left heart base and are considered to be physiologic rather than pathologic. The presence of a continuous murmur is consistent with patency of the ductus arteriosus. In most foals the systolic component of the murmur is louder and therefore more obvious than the diastolic component. The murmurs are therefore often described as *holosystolic*, with a point of maximal intensity on the left hemithorax, in the third intercostal space, and at the level of the scapulohumeral joint. Audible continuous murmurs are unlikely to persist for more than 3 days; however, the systolic component of the altered flow may linger for a week or longer in normal animals. It is commonly believed that many neonatal systolic murmurs with a point of maximum intensity over the left outflow tract may be a result of left ventricular ejection rather than flow through the ductus arteriosus. This would be similar to physiologic flow murmurs commonly heard in young adult horses. There are a number of observations that should prompt referral for echocardiographic assessment. These include persistence of any loud murmur, particularly if it is radiating or associated with a precordial thrill, and any signs of cardiac disease including weakness, cyanosis, pulmonary edema, ascites, or unexplained dependent edema. Bacterial endocarditis is rare in the neonate but certainly in older foals should be considered if the cardiac murmur is associated with fever, leukocytosis, and hyperfibrinogenemia. Many congenital heart defects have been reported in foals, with a wide variation in clinical signs and age of presentation. The most common congenital heart abnormality is a ventricular septal defect. Myocardial dysfunction has been reported in association with systemic sepsis in foals. Cardiac troponin I (cTnI) and the cardiac isoenzyme of creatine kinase (CKMB) are both elevated in foals with sepsis, although the elevation does not accurately predict survival.[26]

17.4.6 Respiratory Tract

The respiratory rate, rhythm, and depth should be assessed as part of the physical examination of the neonate. The respiratory rate and tidal volume are markedly increased during the first 60 minutes of postnatal life. Rates approaching 80 breaths per minute are not uncommon during this time, after which there should be a steady decrease to approximately 30. Respiratory rhythm will vary with the level of consciousness. In foals with hypoxic-ischemic brain disease, periodic breathing patterns are common, including Cheyne-Stokes and erratic rhythms that may include lengthy apneic pauses, occasionally exceeding 30 seconds. *Cheyne-Stokes respiration* refers to periods of apnea and hypopnea that alternate with periods of hyperventilation. Both respiratory frequency and tidal volume are affected.[27] It is possible that periodic breathing may contribute to the pathology associated with the syndrome. Auscultation of the respiratory tract is an essential part of the examination but can be misleading. Moist rales are normally present throughout the respiratory cycle after birth because of residual fluid within the airways. Asymmetry of air movement and end-inspiratory crackles are also normal findings as a result of simple atelectasis of the dependent lung during lateral recumbency. These typically resolve within minutes of standing. Conversely, foals can have significant lung disease yet few abnormal findings on thoracic auscultation. Added to this problem is the absence of cough and nasal discharge in many neonates during the early phases of lower airway disease.

Thoracic trauma and rib fracture can occur as a complication of second-stage labor. Costochondral dislocation can occur in as many as 20% of births. Fractures of the rib shaft occur far less commonly and can on rare occasions cause significant clinical disease and death. This can include hemothorax, lung laceration and

pneumothorax, and pericardial and myocardial puncture. Diagnosis is by observation of thoracic wall symmetry and synchrony, palpation, and imaging (ultrasound or radiography). Management is typically conservative unless displacement of shaft fragments is identified over key underlying structures.

17.4.7 Oral Cavity and Nasal Passages

Oral mucous membranes should be assessed for color, moisture, and refill time. Normal foals have membranes that are moist, are pale pink, and have a capillary refill time (CRT) of approximately 1.5 to 2 seconds. Given the importance of the intestinal system in the genesis of neonatal sepsis, it is recommended that the veterinarian have clean hands, or preferably be gloved, during this part of the overall examination. In the initial stages of systemic sepsis the membranes develop a bright red color with a brisk CRT. This is usually accompanied by episcleral congestion and reddening of the coronary bands. As septic shock ensues, the membranes darken and the refill time becomes prolonged. The presence of mucosal hemorrhages is most consistent with disseminated intravascular coagulation (DIC) associated with advanced systemic sepsis. A rare cause of mucosal petechial hemorrhages is neonatal alloimmune thrombocytopenia. Affected foals may demonstrate prolonged bleeding after routine venipuncture. A subset of affected animals may also have oral and lingual vesicles and ulcers and widespread ulcerative dermatitis with crusting. These foals are typically weak and are reluctant to suck from the dam because of oral pain. The condition appears to be self-limiting and resolves within 2 weeks, presumably because of removal of alloantibodies. Icterus of the oral mucous membranes can occur in association with bacterial or viral sepsis, as a consequence to hemolysis (as in neonatal isoerythrolysis or certain clostridial infections), or as a benign process, idiopathic neonatal hyperbilirubinemia. In hemolytic diseases of the newborn the yellow discoloration of the membranes is often superimposed on pale membranes. Blue or blue-gray discoloration of the membranes can occur with severe hypoxemia or circulatory collapse. Cyanosis can result from pulmonary or cardiac causes. The nasal passages should be examined for fluid or discharge. The presence of orange to brown fluid at the nares immediately after birth is consistent with meconium aspiration. Passage of meconium into the amniotic sac indicates prepartum stress.

267

268

Dental problems are uncommon in newborn foals with the exception of problems associated with facial deformities, such as maxillary prognathism, mandibular prognathism, and campylorrhinus. The central incisors usually erupt during the first 5 to 7 days of life. The middle incisors rise between 4 and 6 weeks of age, but the corner incisors do not erupt until 6 to 9 months. In miniature horses and ponies the eruption of the middle and corner incisors is delayed at 4 months and 12 to 18 months, respectively. The 12 temporary molars are present at birth or erupt within the first week of life. *Maxillary prognathism* or *parrot mouth* describes the condition in which the mandible is shorter than the maxilla, producing an overjet or overbite. The condition may affect the incisors, check teeth, or both. It is the most common congenital oral malformation of foals. The incidence has been reported to be 2% to 5%. Severe manifestations of the condition often coexist with other developmental abnormalities. A genetic basis is suspected (simple autosomal recessive) but has not been definitively established. *Mandibular prognathism* or *sow mouth* describes the condition in which the maxilla is shorter than the mandible, producing an underbite. It occurs less commonly than the maxillary equivalent. *Campylorrhinus (wry nose, wry face)* describes the condition in which the premaxilla and nasal septum are deviated laterally. The condition may occur singularly or in combination with other deformities, such as wry neck, cleft palate, and maxillary or mandibular prognathism. If the deviation is severe, the foal may have great difficulty in sucking from the mare. There may also be problems with breathing. However, in most foals the deviation is mild and represents a simple but obvious cosmetic defect. As with other facial deformities a heritable basis is possible; therefore breeding is not recommended. Cleft palate is an uncommon congenital defect of foals that results from incomplete fusion of the lip and/or secondary palate during the early gestational period. It has an estimated incidence of 0.1% to 0.2% of all births. Almost all clefts occur in the secondary palate, the horizontal partition dividing oral and nasal cavities. The secondary palate includes all of the soft palate and most of the hard palate,

with the majority of the defects restricted to the soft palate. The basis of this congenital defect is not known but could include a heritable component and/or exposure of the developing fetus to infection, toxins, or nutritional disturbances.

The most common clinical sign is nasal regurgitation of milk immediately after sucking. Foals with small-palate defects may have intermittent milk drainage from the nostril and consequently escape diagnosis during the neonatal period. There are rare reports of cleft palates being initially diagnosed in adult horses. Most will develop an aspiration pneumonia that can be difficult to identify in its early stages because of immaturity of cough receptors. Surviving foals will typically be poorly grown and ill-thrifty. The diagnosis is usually straightforward and centers on an appropriate history and signalment. Confirmation is through palpation using the third finger or by direct inspection of the oral cavity. Smaller defects may be detected by endoscopic examination of the nasal passages or through the oral cavity under anesthesia. Oral palpation is recommended for all sick neonatal foals before commencing potentially costly treatment.

The presence of milk at the nares after feeding is not considered pathognomonic for a cleft palate. Many foals with this condition do not have the defect but rather delayed or altered coordination of the swallowing reflex. Clinical signs may be noted as early as a few hours of age and persist variably from hours through weeks. The basis of the condition is not known, but generalized weakness, hypoxic-ischemic brain disease, and nutritional myodegeneration (white muscle disease) have all been suggested as possible causes (Box 17-2). Soft-palate displacement may also occur in newborn foals as a result of a persistent frenulum between the ventral aspect epiglottis and base of the tongue or with hypoplasia of the epiglottis.[28] Chronically affected foals develop signs consistent with aspiration pneumonia, including cough, ill-thrift, and failure to grow. The diagnosis is confirmed through endoscopy of the nasopharynx; persistent dorsal displacement of a flaccid soft palate and dorsal collapse of the nasopharynx are typical findings. The palate will not replace during attempts to swallow. The procedure is important to rule out congenital defects of the palate and epiglottis, although endoscopy of the oral cavity under short-acting anesthesia may be necessary to rule out more obscure problems such as persistent frenulum or epiglottic hypoplasia. Radiography and ultrasound are useful diagnostic tests to confirm the presence and extent of a ventral consolidating pneumonia. Pharyngeal and subepiglottic cysts are uncommon in newborn foals but when present may be associated with dysphagia and nasal regurgitation of milk. Other clinical signs may include a respiratory noise, cough, and dyspnea. Diagnosis is by endoscopy and radiography. Treatment options include ablation using sharp dissection, laser ablation, or a snare.[29] Esophageal diseases are rare in the newborn foal. Reported conditions include congenital dilatation or ectasia, tubular or cystic esophageal duplication, megaesophagus, motor dysfunction, and stricture. Most descriptions are in foals outside of the neonatal period.

17.4.7.1

Box 17-2 Differential Diagnoses of Nasal Regurgitation of Milk

Cleft palate

Persistent dorsal displacement of the soft palate

Pharyngeal and subepiglottic cysts

White muscle disease

Hyperkalemic periodic paralysis

Guttural pouch tympany

Prematurity or dysmaturity

Forced bottle feeding

Esophageal disease

17.4.8 Eyes and Associated Structures

Several ocular features are unique to the newborn foal. These include a round pupil, reduced corneal sensitivity, prominent lens Y sutures, and persistence of blood in hyaloid artery remnants. The optic disc tends to be round rather than oval and has smooth margins. Normal newborn foals lack the ability to completely close their eyelids (lagophthalmos).[30] Entropion is one of the more common ocular problems in newborn foals. The condition primarily affects the lower lid and involves inward rolling of the lid margin such that the eyelid hairs may cause abrasion to the cornea. It rarely occurs as a primary event and is usually secondary to dehydration or emaciation. Temporary eversion using vertical mattress sutures or staples is highly effective at reducing the risk of corneal damage; a less preferred method involves subcutaneous injection of procaine penicillin into the lid. Surgical treatment for entropion is rarely indicated and should be reserved for older foals only. Corneal ulceration occurs commonly in sick neonatal foals. An important feature of the newborn foal is significantly reduced corneal sensitivity when compared with adult horses.[31] This may in part explain why the signs of corneal disease in foals differ markedly from similarly affected adults. Cardinal signs of keratitis, including blepharospasm, photophobia, and excessive lacrimation, are often absent in the early stages of disease in neonates. There are a number of risk factors for corneal abrasion in foals, including the high prevalence of entropion, the propensity for prolonged recumbency, and the frequency of seizures and colic. The key to management is early recognition. In many hospital practices daily fluorescein staining is part of the routine management of most sick foals. The frequent use of lubricating ointments may also play an important prophylactic role in preventing eye disease.

268

269

Careful examination of the globe may reveal signs of iridocyclitis. This can be unilateral or bilateral and usually is regarded as an ocular manifestation of systemic sepsis. In very young foals the presence of fibrin or hypopyon may indicate in utero bacterial exposure, often caused by placental infection. Likely the most common cause of blindness during the neonatal period can be directly or indirectly linked to asphyxial brain injury. In many of these foals the loss of vision is attributable to cortical disease, as pupillary light reflexes are usually preserved. The prognosis for future vision is usually good. Cortical blindness can also result from prolonged generalized seizures. The menace response is not a reflex and is considered to be a learned behavior in newborn foals. The characteristic eyelid blink and ocular retraction may be absent during the first 1 to 2 weeks of postnatal life, but most foals still demonstrate head withdrawal in response to a threatening hand gesture, assuming an adequate level of alertness. Neonates should blink when a bright light is directed into the eye (bright light blink or dazzle reflex) and should have brisk direct and consensual pupillary light reflexes.

There may be a slight ventromedial rotation of the eyeballs in normal foals; this persists for the first month.[16] Spontaneous nystagmus in any direction is abnormal, but vestibular nystagmus is present when the head is moved in a horizontal plane in healthy foals. The fast phase of the nystagmus is in the direction of head movement. Subconjunctival and scleral hemorrhage is a feature of foals born after dystocia. This can be an

important warning sign of impending postasphyxial problems such as hypoxic-ischemic encephalopathy. The sclera should also be examined for signs of blood vessel congestion, a feature of sepsis, and for icterus. The differential diagnosis for neonatal icterus is discussed elsewhere. Most foals with an abnormally small globe (congenital microphthalmos) are blind, have a reduced palpebral fissure, and have a prominent nictitans.[30] The condition may be unilateral or bilateral, and it has been suggested that thoroughbred foals may be more commonly affected.[30] Foals are at increased risk for ulceration resulting from associated entropion. Microphthalmia has been reported to occur along with mandibular prognathism and cleft palate in foals exposed to griseofulvin during the second month of gestation.[32] Congenital cataracts are relatively common eye defects in foals. Veterinarians should be careful not to misinterpret lens sutures as cataracts. These Y-shaped sutures may persist for up to a year. Assuming a normal retina, an absence of uveal tract inflammation, and an appropriate demeanor, most of these foals are candidates for surgery. Other abnormalities include atresia of the nasolacrimal system, dermoids, retinal dysplasia, and optic nerve hypoplasia.

17.4.9 Ears

Ear problems occur uncommonly in foals. It is, however, important to examine the inside of the pinnae for dermal ecchymotic or petechial hemorrhages. Foals with systemic sepsis may develop these lesions.

17.4.10 Thyroid Gland

Hypertrophy of the thyroid gland (goiter) can occur in response to deficient or excess dietary iodine. One of the more common reasons for thyroid gland enlargement in neonatal foals is excess iodine supplementation during pregnancy.[33] There are reports of neonatal goiter when seaweed was incorporated into the diet of broodmares[34] or when pellets that had been formulated with excessive iodine were fed to mares.[35] Dysmature foals with thyroid hyperplasia and concurrent musculoskeletal problems have been identified in western Canada and the northwestern United States.[36,37] The syndrome results in hypothyroidism and may be related to the feeding of diets that are high in nitrate or low in iodine to mares during pregnancy. Thyroid hormone is an important cofactor in maturation of the respiratory system, and hypothyroidism has been linked to respiratory failure in a newborn foal.[38] In older foals, enlargement of the thyroid has been associated with dietary iodine deficiency and low circulating levels of T_4.[33] Newborn foals have baseline T_3 and T_4 levels that are considerably greater than those of adult horses.[39] These levels decline over the first 12 days after birth. Normal day-old foals have a doubling of T_3 at 3 hours and a 16% increase in total T_4 at 6 hours after TSH administration.[40]

17.4.11 Neck and Back

There are a number of congenital anomalies that affect the alignment of the vertebral column. These include atlantoaxial malformations, scoliosis, kyphosis, lordosis, and combined anomalies, such as kyphoscoliosis. Atlantoaxial malformations may occur with or without cervical scoliosis or signs of spinal cord compression. Arabian foals are most commonly affected, and a familial predisposition has been suggested.[41] There may be palpable abnormalities of the atlas and axis and altered head carriage. The diagnosis is confirmed using radiography, with which a range of abnormalities is seen including atlantooccipital fusion, hypoplasia of the dens, and axis malformation. Prognosis is very poor, as many foals have signs of ataxia and paresis involving all four limbs at birth. Some animals may have normal neurologic function. Foals with severe kyphosis or kyphoscoliosis often have underlying malformation of the thoracic vertebrae.[42]

17.4.12 Gastrointestinal Tract

Borborygmi should be easily heard in healthy neonates. Assessment of abdominal size and shape is part of the routine physical examination. This is critical in assessment of the foal with abdominal pain or decreased urine output. In contrast to small animals, in neonatal foals abdominal palpation is usually unrewarding. In small foals with relaxed abdominal muscles it may be possible to palpate meconium impactions and the urinary bladder. When abdominal distention is present, it is important to determine if it is a result of fluid or gas accumulation. Ultrasound has become an essential tool in the assessment of abdominal distention.

The routine administration of an enema is performed commonly in healthy newborn foals in an attempt to reduce the straining associated with the passage of meconium. Various methods are used, with commercial glycerine phosphate—based products the most common. These are relatively easy to administer, although care should be taken to avoid direct trauma to the rectal mucosa with the applicator tip. Most veterinary practices probably use gravity enemas of 400 to 800 mL of warm soapy water delivered through a soft tube, such as a canine stomach tube or male urinary catheter. Acetylcysteine retention enemas are not administered routinely, but rather in foals with resistant meconium impactions.

269 270

Coprophagy is observed in normal foals from birth through 5 to 6 months of age.[43–45] Most foals demonstrate coprophagy by 7 days of age. The consumption of feces is not driven by hunger, and foals have a selective preference to consume feces of their dams. The most likely basis for coprophagy is as a mechanism to populate the intestinal tract with bacteria, fungi, and protozoa essential for digestion of an herbivorous diet. Coprophagy precedes the passage of protozoa in foal feces and the development of the syndrome known as “foal heat diarrhea.” This is a benign diarrheal disease of newborn foals and should not require treatment.

17.4.13 Umbilicus

Breakage of the umbilical cord occurs naturally within 5 minutes of birth, with the natural break typically 2.5 to 7 cm beneath the body wall. Immediate postpartum transfusion of blood from the placenta to the foal is important, although the process is essentially complete within minutes, assuming establishment of a respiratory rhythm. Premature breakage of the cord can result in significant blood loss—up to one third of the circulating fetal blood volume.[46] Hemorrhage should therefore be controlled with a commercial clamp or umbilical tape. Prolonged attachment of the cord is unlikely to be a significant problem, although blood flow between the placental membranes and the foal is partly gravity dependent, such that blood could flow preferentially from foal to membranes if the foal is above the level of the placenta. Manual breakage of the umbilical cord is recommended if it remains attached for more than 8 minutes. The preferred method for manual cord breakage is to grasp the placenta side of the cord while holding the foal side of the cord with the other hand to prevent excessive traction on the abdominal wall. Gently twist and pull from the placenta side such that the breakage will occur at the natural site of detachment. The umbilical cord should not be cut, as this does not promote normal retraction of the umbilical structures. The cut umbilical stump usually remains prominent, often with detectable pulse, and is more likely to be associated with hemorrhage or patency of the urachus. Bleeding from the umbilicus can also occur after apparent closure if the foal is straining to either defecate or urinate. Clamping or tying off the stump again can reduce this. The exposed umbilical stalk is a portal for bacterial entry. Any manipulation of the cord should be performed with clean, gloved hands. Routine disinfection of the stump is strongly recommended during the first 2 days of postnatal life or until the stump has dried. Most hospitals use 0.5% chlorhexidine solution as the preferred dipping agent, but some advocate a 2% iodine solution for use by clients, as its use can be verified by the characteristic iodine staining.

The appearance of the umbilical stump changes over the first few days after birth. The external stump should be examined for size and moisture. A complete assessment of the umbilical remnants requires ultrasound. The most common problems of the umbilical stump are patency of the urachus and infection. Tearing of the urachus as it moves through the body wall can produce a circle of cellulitis around the stump because of leakage of urine into the tissues.

Umbilical hernias occur relatively commonly in foals. The condition is generally considered to be a congenital defect with a likely hereditary basis, although umbilical infection may be an important postnatal predisposing factor in some foals. In a study from the Netherlands 19 of 44 Dutch Warmblood foals had a palpable abdominal wall defect varying between 2 and 6 cm at the time of birth.[47] In all but one of these foals the defect had closed by 4 days of age. Of interest was that approximately 28% of the foals developed a defect at 5 to 8 weeks of age. These were considered to be true umbilical hernias in that a hernial sac with contents was palpable in addition to the abdominal wall defect. The group included both foals with and foals without a palpable abnormality at birth. In a retrospective study of hospitalized foals it was concluded that the defect was more likely to occur in fillies than in males and that the condition was more common in thoroughbreds than in standardbreds.[48] Most clinicians recommend delay in treatment, as some defects will close spontaneously. Several techniques have been described for repair and vary from external clamps to surgical herniorrhaphy. Rare complications are associated with umbilical hernias or their repair. These include enterocutaneous fistulas, umbilical abscessation, and intestinal incarceration.[49,50]

17.4.13.1

Diagnosis of Umbilical Disorders Using Ultrasound

JOHN E. MADIGAN

Ultrasonography has been used to quantitatively correlate umbilical structural changes with age in foals. Mean diameters for selected umbilical structures derived from 13 foals ranging from 6 hours to 4 weeks of age have been reported.[50a] Foals may be examined in a stall adjacent to their dams and near the stall door. Foals are made to lie down without sedation, using the method shown in Fig. 17-1. Foals will usually become quiet and still within a few minutes of recumbency. All ultrasound examinations are performed with the foal in left lateral recumbency with the ultrasound machine behind the examiner (Fig. 17-2).

Fig. 17-2 includes a diagram of the anatomic locations of the structures examined during the ultrasound evaluation. A 5- to 8-cm-wide strip of hair can be clipped along the ventral midline, extending from the umbilical stump cranial to the xiphoid to facilitate examination of the umbilical vein. In addition, an area 5 cm by 5 cm caudal to the umbilical stump is clipped to visualize the umbilical arteries and urachus. The ultrasound examination is performed with a 7.5-MHz sector scanning transducer; a built-in standoff is preferred. Eight views of the umbilical vessels and linear measurements of the vertical and horizontal dimension of each vessel can be taken. This allows examination of the umbilical vein (three views) and umbilical stump (one view) (Fig. 17-3), and urachus/umbilical arteries (four views) (Fig. 17-4). The umbilical vein is visualized at a site approximately 1 cm cranial to the umbilical stump (view 1); another view taken approximately halfway between the umbilicus and the liver (view 2) and at a point where the vein curves away from the body wall and angles toward the liver (view 3). A single cross-sectional view of the external umbilical stump is made at the body wall. The combined urachus/left and right umbilical artery is visualized in a single cross-sectional view just caudal of the umbilical stump. The comparative mean umbilical vessel diameter normal data is summarized in Table 17-5. All but one of the ultrasound views demonstrated a significant reduction in mean vessel diameter over the first 7 days of life in normal foals; only the urachus and

umbilical arteries in a single structure remain static during the first week of life. Enlargements in these structures are suggestive of inflammation, infection, or hematoma and should be correlated with clinical signs and laboratory findings for choosing an optimal treatment plan.

270

271

Fig. 17-1 Procedure for placing neonatal foals in lateral recumbency for umbilical ultrasound. **A,** The foal is restrained by placing the arms around the neck area and rump and holding the tail. **B,** The left forearm of the handler is placed against the head of the foal, and the head is folded back toward the rump area while pressure is applied to the rear quarters with the other arm. **C,** The foal leans backward and sags toward the handler, becoming recumbent. **D,** The foal is allowed to sag to the ground and is kept in the folded position until completely recumbent and relaxed. **E,** The front legs are then grasped with left hand and the forearm is placed on the neck area. The rear legs are held with the right hand. **F,** The foal is held steady in this position until blindfolded and struggling stops. The foal is in left lateral recumbency.

17.4.14 Urogenital System

Urine is one of the most important indicators of health in foals. Normal neonatal foals produce a large volume of urine relative to their bodyweight; estimated at 148 mL/kg/day, this value is approximately fivefold to tenfold greater than that of a healthy adult horse on a per kilogram of bodyweight basis.[51] The urine should be light in color and low in specific gravity. Any foal observed to pass thick, concentrated urine should be assessed closely. The first passage of urine after birth occurs around 8-9 hours of age.[52] Colts will pass urine earlier than fillies, at approximately 6 hours of age in colts and 11 hours in fillies. Disruption to the urinary tract occurs relatively commonly and can be difficult to diagnose early in the clinical course. Rupture of the urinary bladder during delivery occurs more commonly in colts than in fillies, although postpartum disruption to the tract in sick or hospitalized foals has no gender bias.[53,54] Signs often include prolonged straining, passage of small volumes of urine, progressive abdominal distention, lethargy, and weakness.

In colt foals the inguinal and scrotal region should be palpated for swelling and testicular descent. Inguinal and scrotal hernias occur relatively commonly but rarely result in clinical signs. Preputial edema may be present. Most congenital hernias are indirect, unilateral, and easily reducible and spontaneously resolve by 3 to 4 months of age. Positioning the foal on its back facilitates manual reduction. A figure 8 support wrap can assist in keeping the hernia reduced. Surgical correction is recommended if spontaneous resolution is delayed, if the hernia increases in size, or if signs of colic develop. Certain breeds appear to be at increased risk for herniation, including Tennessee Walking Horses and standardbreds. A rent in the parietal vaginal tunic can lead to subcutaneous dissection of intestinal loops; this requires surgical reduction, herniorrhaphy, and unilateral castration.[55] Although such rents are extremely uncommon in foals, signs of colic can occur if herniated loops of intestine strangulate.

At the time of birth most testes lie within the inguinal canal. The extraabdominal gubernaculum typically limits movement into the scrotum. The mass of gubernaculum can easily be mistaken for the testicle. Monorchidism has been reported in foals, and affected colts are usually mistaken as cryptorchids.[56] Congenital abnormalities of the penis are rare. Failure to drop the penis during urination can occur as a consequence of preputial edema, a common complication in colts that are straining to defecate or urinate. The free part of the penis is normally fused to the internal lamina of the prepuce for up to 1 month of age. This can make exteriorization of the penis difficult. “Kinking” of the penis has been described, resulting in stranguria or pollakiuria.[57] Correction was achieved through manual straightening of the penis.

273 274

17.4.15 Musculoskeletal System

Supplementation of foals with selenium is recommended for those born in known selenium-deficient regions when mares have not been supplemented during pregnancy. Severe rhabdomyolysis has been reported in newborn foals, usually associated with selenium deficiency.[58] Glycogen branching enzyme deficiency is an inherited cause of mortality in quarter horse foals.[59] Clinical signs are variable and include seizure, persistent recumbency, respiratory failure, and cardiovascular collapse. Authors of the original report suggested that the generalized nature of the clinical signs would likely lead to a false diagnosis of other, more common neonatal diseases.

Because of the rapid growth that occurs in the first months of life, any orthopedic condition must be identified and immediately managed in order to achieve a successful long-term outcome. Palpation of synovial structures is

a critical part of the foal physical examination, regardless of whether lameness or synovial distention is present. Persistent recumbency, a common feature of generalized sepsis, can make detection of joint infection difficult. Synovial sepsis is a common manifestation of bacterial infection, and most affected foals will be lame with obvious joint distention and heat on palpation. Diagnosis is confirmed through synoviocentesis. An elevated synovial fluid white blood cell (WBC) count (>20,000 cells/μL), a predominance of neutrophils (>90%), and an elevated protein concentration (>4 g/dL) all point toward sepsis. Osseous infection can also be difficult to identify in its early stages. Common sites include the stifle, hock, and distal physis of the cannon bone. Osteomyelitis should be suspected in any foal with lameness and edema, heat, and pain on palpation of the overlying tissues. Trauma by the mare is often suspected, but osseous infection should always be considered, particularly in foals with other manifestations of sepsis (e.g., omphalitis, diarrhea, uveitis). There may or may not be effusion in adjacent joints, and if present it could reflect either an extension of the septic process or a nonseptic “sympathetic” effusion. The management of synovial and bone infection is discussed elsewhere.

Contractural deformities of the limbs occur commonly in newborn foals. These are considered to be congenital and may result from a variety of causes including malpositioning within the uterus. If the foal is able to stand and ambulate, most mild deformities of the carpus, fetlock, and coffin joint will resolve within 4 to 5 days without specific treatment.[60] Moderately to severely affected foals often require splinting in combination with medical therapy in order to achieve a successful outcome in the shortest possible time. Foals with persistent or prolonged recumbency are very susceptible to secondary problems, the most important being sepsis and corneal abrasion. Medical therapy often includes judicious use of oxytetracycline and nonsteroidal antiinflammatory drugs. Rupture of the common digital extensor within the synovial sheath may occur in foals with contractural or flexural deformities. This should be suspected in foals with a soft, nonpainful swelling over the dorsolateral aspect of the carpus. Gait may appear stilted, and there may be knuckling of the fetlock. Most foals quickly regain extensor function, and the long-term prognosis is good.

Hyperextension or joint laxity is common in premature and dysmature foals. The most common presentation involves dropping of the fetlock, hyperextension of the pastern, weight bearing on the heel bulbs, and tipping upward of the toe. Again, most foals improve spontaneously over 3 to 4 days, but heel extensions and light padding to protect the heels from bruising will hel more severely affected foals. Hyperextension of the carpus is also observed in some foals.

Angular limb deformities are also frequently encountered in practice; the most common deviations are carpal and tarsal valgus and fetlock varus. Examination should include observation at rest from front and rear, paying careful consideration to any external rotation of the limbs, which may give a false impression of limb valgus. In weak or premature foals there may be limb deviation resulting from ligamentous laxity; this is best assessed through limb palpation including flexion and observation of the foal at the walk. If the limb can be straightened manually, then the deviation is due to ligamentous laxity or delayed ossification of the cuboidal bones.[60] There is a variety of conservative and surgical approaches to these foals.

Laminitis with sloughing of the hoof capsule can occur in neonatal foals; however, it is rare and is typically associated with significant systemic disease. Polydactylism is a duplication of all or part of the digit. This condition can occur as a single defect or as part of a group of congenital anomalies. Surgery may be indicated when the condition occurs as a single entity, not only to improve the cosmetic appearance but also to reduce the risk of lameness at a later age.

17.5 POSTPARTUM ASSESSMENT, PHYSICAL EXAMINATION, AND CARE OF NEWBORN RUMINANTS

John K. House

17.5.1 Neonatal Behavior

Calves and lambs normally have a head-righting reflex almost immediately after birth. Sternal recumbency is usually attained within 2 to 3 minutes, followed rapidly by attempts to stand, at 10 to 20 minutes for lambs and 15 to 30 minutes for calves.[61,62] Hypoxic neonates may struggle and appear bright initially but have difficulty maintaining sternal recumbency, have depressed or absent suck reflex, are slow to stand or remain recumbent, and develop a depressed mentation within hours. After experimentally induced hypoxia, nonviable hypoxic calves had heart rates (118 ± 36 bpm) and body temperatures (39.6° C ± 0.2° C) similar to those of viable calves but lower respiratory rates (14 and 18 versus normal 49 ± 12).[61] In cattle the average time from birth to standing and nursing varies according to breed. The average time from birth to standing and nursing for beef calves is 35 and 81 minutes, respectively. Dairy calves take approximately twice as long.[63] Small ruminants are generally quicker to stand and nurse than calves, with most lambs standing within 30 minutes[62] and nursing within 90 minutes of birth. Failure of the newborn to nurse may result from reduced neonatal vigor, poor mothering, poor maternal conformation, or adverse conditions such as slippery flooring. Calves have difficulty locating teats on low-slung udders (less than 45 cm from the ground)[64] and difficulty nursing from teats greater than 35 mm in diameter.[65] Observation of interaction between the newborn and dam in the immediate postnatal period allows early recognition of the compromised neonate and facilitates timely intervention if maternal conformation or behavior threatens to impede the neonate's efforts to nurse.

274

275

Abnormal neonatal behavior in the immediate postnatal period is commonly secondary to perinatal hypoxia. Resuscitation of the newborn is discussed in Chapter 16. In utero infections and congenital neurologic abnormalities should also be considered as possible causes of abnormal neonatal behavior. Collection of sera before feeding colostrum is useful for diagnosing in utero infections. Precolostral serum immunoglobulin concentrations in calves are very low (IgM 0.126 ± 0.015 mg/mL, IgG 0.044 ± 0.003 mg/mL).[66] Elevated serum concentrations of immunoglobulins before ingestion of colostrum may be observed with in utero infections.[66] Specific serologic tests are available for Cache Valley virus, Akabane virus, bovine virus diarrhea (BVD) virus, *Neospora* species infection, *Toxoplasma* infection, and bluetongue virus.[67] Teratogens and inherited diseases that may cause the birth of weak neonates are listed in Box 15-3.

Tube-feeding colostrum during the first 12 hours of life is appropriate if free-choice consumption is questionable. Drying, warming, and tube-feeding colostrum may revive weak newborn lambs and kids. Tube-feeding dairy calves 3 L of colostrum at birth is recommended, as failure of passive transfer is high (61%) in dairy calves left to nurse their dams.[68]

Table 17-6 Normal Hematology Reference Values for Neonatal Calves[118,119]

	Age			
Parameter	**Birth**	**24 Hours**	**48 Hours**	**3 Weeks**
RBC (×10^6/μL)	9.35 ± 1.02	8.17 ± 1.34	7.72 ± 1.09	8.86 ± 0.68

17.5.2 Maternal Behavior

Failure of maternal bonding is more common with primiparous dams, with multiple offspring, and after delivery via caesarean section. Restraint and patience often pay off. Reluctant dams will often accept the calf after several days of restrained feeding in which the dam is placed in a crush two or three times a day to allow the calf to nurse. Maternal bonding in sheep is mediated by an olfactory mechanism.[69] Parturition alters the release of monoamines, amino acids, and oxytocin within the olfactory bulb, stimulating an attraction to amniotic fluid and acceptance of the lamb.[70] Artificial vaginocervical stimulation with a gloved hand induces similar alterations in the release of monoamines, amino acids, and oxytocin within the olfactory bulb and is useful for triggering formation of maternal bonds to foster lambs for at least 27 hours postpartum.[70]

17.6 PHYSICAL EXAMINATION

An initial assessment of the sick neonate should be made to determine if there is a need for immediate intervention and stabilization. Particular attention should also be paid to identification of any congenital malformations. The key to conducting a thorough physical examination is the development of a systematic approach. Normal parameters for calves are listed in Table 17-6.

17.6.1 Examination from a Distance

The physical examination begins with examination from a distance with assessment of behavior, body condition, and stance. Drooping of the head and ears is an early sign of illness. Sick calves spend increasing amounts of time recumbent and are less inclined to drink. In beef calves, lambs, and kids this may be reflected by udder distention in the dam. With dairy calves the calf feeder reports the calf requires stimulation to stand and fails to drink. Resting respiratory rate and effort are assessed before the calf is handled. Abdominal contour should be noted, with consideration of the neonate's reported appetite; an apparently normal abdominal contour may be abnormal if the calf has not eaten for several days. Observing the neonate navigate its environment provides a simple assessment of vision.

275 276

17.6.2 Physical Appearance, Bodyweight, and Body Condition

Congenital disorders may cause subtle changes in physical appearance and behavior. For example, Saler calves with β-mannosidosis have moderately domed heads, mild superior brachygnathism, and a slight head tremor.[71] Similarly, in utero infections that lead to growth retardation may be reflected by low birthweight and poor body condition.

17.6.3 Body Temperature

Rectal temperature in calves ranges from 99° F to 102° F (37.2° C to 38.9° C) during the first 4 days after birth. Calves with sepsis are often febrile; however, absence of a fever does not rule out sepsis. Calves in septic shock

may have subnormal temperatures. Premature calves are prone to hypothermia.[72] Hyperthermia during the first week of life has been reported to be common in cloned calves.[73]

17.6.4 Cardiovascular System

Peripheral pulses in the tail and brachial arteries should be strong and regular, and the peripheral extremities warm. Mucous membranes should be moist and pale pink with a CRT of <2 seconds. Gray or cyanotic mucous membranes are associated with severe hypoxia (i.e., PaO_2 < 35 to 40 mm Hg) and/or circulatory collapse as seen with hypotensive, endotoxic, or hypovolemic shock. Cardiac and pulmonary causes of cyanosis must be distinguished. Cyanosis secondary to cardiac causes reflects right-to-left shunting of blood, as may be observed with tetralogy of Fallot or ‘Eisenmenger's complex.

Dyspnea and coughing are often the predominant clinical signs of congestive heart failure in calves. Close examination may reveal distention of the jugular veins and brisket edema, but if heart failure is predominantly left sided these signs may be absent. Cardiomyopathy secondary to selenium deficiency or gossypol, monensin, or lasalocid toxicity may manifest as a syndrome of sudden death during periods of excitement precipitated by feeding or moving calves out of hutches into group pens.[74]

Cardiac arrhythmias are observed sporadically in neonates, often associated with diarrhea. Metabolic acidosis secondary to losses of electrolytes and water causes a transcellular shift of potassium ions into the extracellular fluid in exchange for hydrogen ions.[75] As serum potassium increases (>5.5 mEq/L), aberrations in cardiac excitability occur and are manifested as progressive atrial standstill, progressing to ventricular fibrillation and asystole.[76] Tachyarrhythmias may be observed in calves with cardiomyopathies, ionophore toxicosis,[77] or hypomagnesemia.

The most common cardiac defect in the large animal neonate is a ventricular septal defect, but a variety of other malformations have been described and are discussed in Chapters 6 and 30. Ancillary tests for evaluating the cardiovascular system are discussed in Chapter 30.

17.6.5 Respiratory Tract

The respiratory rate and effort of breathing in neonates are best observed from a distance so that the stress of restraint does not influence the assessment. Lung sounds of neonates are typically easier to hear than those of adults; however, lung sounds do not always correlate well with the severity of pulmonary pathology present. Thoracic percussion is also easier to perform in the neonate and can be useful to identify the presence of cranioventral consolidation. Animals with few or no audible thoracic abnormalities may have severe respiratory disease. The rate and effort of breathing are important to consider in the physical assessment of respiratory function. When available, chest radiology, thoracic ultrasonography, and arterial blood gas analysis are useful ancillary diagnostic tools.

Lung disease in the newborn is usually diffuse and is the result of infection acquired in utero or postpartum and/or lung atelectasis associated with immaturity, recumbency, or surfactant dysfunction. Signs of lung disease include increased work of breathing characterized by nostril flare, rib retractions, and increased abdominal effort. A cough and nasal discharge, salient features of respiratory disease in older neonates, are infrequent findings in newborns with lung disease.

Conditions that cause partial occlusion of the upper airway, such as necrotic laryngitis, often induce pronounced inspiratory stridor. Expiratory stridor and increased and prolonged expiratory effort are usually associated with lower airway disease. A malodorous breath may be present with necrotic pharyngeal injuries, necrotic laryngitis, or aspiration pneumonia. Age is an important signalment for respiratory disease in calves. Enzootic pneumonia is common in calves between 4 weeks and 6 months of age but uncommon in calves less than 4 weeks of age. Outbreaks of pneumonia in calves less than 4 weeks of age are occasionally observed in calves fed milk contaminated with *Mycoplasma* species.[78,79] This scenario is one of the risks associated with feeding calves unpasteurized "hospital milk." *Mycoplasma* pneumonia in calves may be associated with arthritis, tenosynovitis, otitis media,[79] and decubital abscesses.[80] Clinical signs associated with mycoplasma otitis include cranial nerve 7 and 8 deficits, unilateral or bilateral ear droop, ptosis, epiphora, head tilt, and recumbency in severely affected calves. Aspiration pneumonia is common in calves less than a week of age, often reflecting inappropriate feeding practices (large holes in teat nipples or poor esophageal tubing technique) or pharyngeal dysfunction.

Periodic apnea and abnormally slow respirations are often the result of metabolic disturbances (e.g., hypoglycemia, hypocalcemia), hypothermia, advanced prematurity, or hypoxia-induced suppression of the respiratory center. Calves with metabolic acidosis usually have an increased respiratory rate with long, deep breaths reflecting respiratory compensation. Tachypnea may be a response to high ambient temperatures, pain, or stress. Congenital defects of the respiratory system in ruminants are rare.

17.6.6 Oral Cavity and Nasal Passages

Hyperemic membranes accompanied by scleral injection are the hallmark of early sepsis. Petechiae on the oral or nasal mucous membranes are consistent with sepsis or thrombocytopenia induced by type II BVD. Ecchymotic hemorrhages may be observed on the sclera with type II BVD infections, with DIC, or after birth trauma. Cleft palate is the most common congenital defect observed in ruminants. Calves with cleft palate may have milk run from the nose and are prone to developing aspiration pneumonia.

276

277

17.6.7 Eyes and Associated Structures

Eyes should be examined for the presence of entropion, ectropion, corneal abrasions or ulcers, uveitis and hyphema, congenital cataracts, microphthalmia, corneal dermoids, scleral injection, and scleral hemorrhage. Scleral hemorrhage is usually the result of birth trauma and can take several weeks to resolve. Icterus is uncommon in neonatal ruminants but may be observed with hemolytic or hepatic disease.

A common cause of corneal edema and ulceration, conjunctivitis, and lacrimation in lambs is acquired or congenital entropion. Acquired entropion is associated with self-trauma, dehydration, or prematurity and the lack of periorbital fat. Entropion should be corrected promptly before serious corneal ulceration and keratitis develop. Mild cases may respond to subcutaneous injections of procaine penicillin G into the lower eyelid. Refractory cases may require placement of vertical or horizontal mattress sutures in the eyelid to correct the problem. The affected eye should be stained to detect concurrent corneal ulceration. Varying degrees of miosis secondary to pain and ciliary body spasm is common. Treatment after correction of entropion includes topical administration of 1% atropine to dilate the pupil and relieve ciliary body spasm and topical antibiotics to prevent bacterial infection.

Uveitis may be observed in the newborn animal exposed to an infected uterine environment or may be a result of generalized infection acquired after birth. Scleral injection suggests and fibrin in the anterior chamber is highly indicative of sepsis.

17.6.8 Ears

Bilateral drooped ear carriage is a common observation in sick calves and should prompt a closer examination. Unilateral ear droop may be observed with otitis and facial nerve paralysis. *Mycoplasma* species, *Pasteurella* species, and *Haemophilus* species are reported to cause otitis in calves. Clinical signs may include facial and vestibular nerve deficits and a purulent discharge from the ear. Calves infected with *Mycoplasma* species may also have tenosynovitis and respiratory disease.

Poor perfusion is reflected by cold extremities. A high incidence of pinna abscesses usually reflects contamination of equipment used to place ear tags.

17.6.9 Neck and Back

Several congenital anomalies affect the alignment of the vertebral column. These include atlantoaxial malformations, scoliosis, kyphosis, lordosis, and combined anomalies such as kyphoscoliosis. Atlantoaxial malformations may occur with or without cervical scoliosis or signs of spinal cord compression. Holstein calves affected by the hereditary condition complex vertebral malformation may display a range of abnormalities that include retarded growth, malformation of the head (dysplasia or palatoschisis), bilateral symmetric flexion of the carpal and metacarpophalangeal joints, posterior arthrogryposis, and interventricular septal defects. Of these, growth retardation, vertebral malformation, and symmetric arthrogryposis are the most consistent findings.[81]

17.6.10 Gastrointestinal Tract

Much can be learned about gastrointestinal function by observing abdominal contour, appetite, and fecal consistency and volume. A normal abdominal contour and vigorous appetite associated with the passage of an appropriate volume of pasty stool suggest normal gastrointestinal function. Congenital defects of the gastrointestinal tract occasionally observed in ruminants include cleft palate, poor jaw conformation (brachygnathism, inferior and superior), atresia coli, atresia recti, and atresia ani. The spiral loop of the ascending colon (spiral colon) is the most commonly affected segment of intestine in calves.[82] Neonates with atresia often have a distended abdomen and a history of a declining appetite. Astute owners may notice the lack of or reduced volume of feces.

In contrast to the adult, in the large animal neonate the rectal palpation of the abdominal structures is of limited value. External palpation of the abdomen can be more rewarding, depending on the cooperation of the individual and the tenseness of the abdominal musculature. In calves it is usually possible to palpate enlargement of the umbilical vein and arteries. The inguinal rings and umbilical area should also be palpated for hernias.

Infectious diarrhea is the leading cause of mortality in calves between 3 and 21 days of age. Typically more than one pathogen is involved and the physical examination provides no indication of the causative agent. Fecal pH may be used as an indicator to distinguish secretory diarrhea (enterotoxigenic *E. coli*) from diarrhea associated with malabsorption and maldigestion. Secretory diarrhea produces an alkaline pH, whereas malabsorption and maldigestion are associated with an acidic fecal pH.[83] Small amounts of blood may be observed in the feces of healthy calves. Passage of blood and fibrin is associated with inflammatory bowel disease induced by pathogens such as *Salmonella* and coronavirus that damage the gastrointestinal mucosa. Infectious agents that cause diarrhea and the ancillary tests available to establish an etiologic diagnosis are discussed in Chapter 20.

Abnormal forestomach function in neonatal ruminants, as in adults, is often reflected by altered abdominal contour as described in Chapter 32. Left and right abomasal displacement and abomasal torsion are observed sporadically in calves. Succussion (simultaneous auscultation and percussion) is useful for delimiting the boundaries of distended visci. Passage of a stomach tube helps distinguish rumen and abomasal distention and facilitates collection of a ruminal fluid sample. A putrid odor to neonatal ruminal fluid is common with putrefactive indigestion when milk is delivered to the rumen in greater quantities than normal by escaping the esophageal groove or via excessive backflow from the abomasum. Reflux of abomasal contents into the reticulum and rumen, independent of feeding, occurs in connection with abomasal inflammation and obstructions.[84] Evaluation of ruminal fluid pH and renin activity are useful for distinguishing abomasal reflux from esophageal groove overflow. Ruminal fluid pH is usually ≥7 with rumen putrefaction, and low to normal with abomasal reflux.[84] Chymosin (renin) is normally present in abomasal juice, and renin activity in ruminal fluid suggests abomasal reflux.[85] Renin activity is measured by adding 2 mL of ruminal juice to 2 mL of whole milk on a CMT (California Mastitis Test) plate. Presence of renin in the ruminal fluid causes coagulation of the casein in the milk. Chloride ion concentration in ruminal fluid from calves is higher than in adults (55 to 102 mmol/L in calves[86] and 25 mmol/L in adults[84]), possibly reflecting the high chloride content of milk (45 mmol/L); therefore the chloride concentration of ruminal fluid is not useful for identifying abomasal reflux in calves.

Abdominal radiographs and/or ultrasound examination can be helpful in diagnosing abdominal problems in the neonate and in distinguishing causes of abdominal distention.[87–89] Transabdominal ultrasonography can be used to locate a suitable site for abdominocentesis. Normal peritoneal fluid from calves has a higher nucleated cell count than that of adult cattle (3350 cells/μl vs 1371 cells/μl). Total protein concentration in peritoneal fluid of calves is similar to that of adults (2.5 g/dL vs 3.1 g/dL).[90]

17.6.11 Umbilicus

Umbilical cord remnant infections represent an important problem in neonates.[91] The infection generally develops during the first 2 weeks of life. Complications associated with umbilical infections include septicemia, septic arthritis, and osteomyelitis.[92] The umbilicus should be examined closely for patency, increased size, moistness or discharge, and tenderness. Abdominal palpation, using both hands and pressing together, is useful for evaluating the umbilicus of ruminants. Enlargement of the umbilical arteries can be palpated coursing caudally toward the bladder, and enlargement of the umbilical vein coursing cranially to the liver. Application of pressure caudal to the xiphoid often elicits a soft grunt from calves with a septic umbilicus and associated peritonitis. Extensive adhesion of bowel to inflamed umbilical structures produces a large, easily palpable intraabdominal mass. Common abnormalities of the calf umbilicus include umbilical hernias, omphalophlebitis, external umbilical abscess, urachal abscess, and omphaloarteritis. Patent urachus is uncommon in calves.

Ultrasound examination of the intraabdominal umbilical structures is a useful ancillary diagnostic tool. Ultrasonography of the umbilical structures of calves has been described by Watson and colleagues.[93] Ultrasound examination of the calf is performed with the calf standing; occasionally the umbilical vein is easier to identify with the patient in left lateral recumbency. The anatomy of the umbilicus of calves differs slightly from that of foals, necessitating alterations in ultrasound technique. In both species the umbilical vein courses from the umbilicus to the liver, which in the calf is located on the right side as opposed to midline in the foal. Also, in cattle the umbilical arteries and urachus retract into the abdominal cavity when the cord ruptures and thus cannot be identified in the external umbilical stalk in normal calves.[93] The umbilical vein of calves is scanned from the umbilical stalk to the liver along the right abdominal wall. The umbilical vein enters the liver

caudoventral to the gallbladder. The umbilical arteries are most easily located adjacent to the urinary bladder and cannot normally be identified much beyond the apex of the urinary bladder unless they are enlarged and abnormal. Identification of a urachal remnant in calves is abnormal.[93]

Literature on the efficacy of navel treatment at reducing calf mortality is divided. In a study of 104 dairy farms, a farm policy of navel treating newborn calves had no significant effect on calf mortality rates. A significant beneficial effect was observed when the navels of calves that had assisted deliveries were dipped with chlorhexidine; other navel treatments such as iodine tended to be associated with increased odds of dying.[94] Navel treatment with iodine was associated with significantly higher mortality in another study of 48 farms; however, the association of navel treatment with mortality on these farms may have reflected the response of producers to high neonatal mortality rather than indicating that iodine navel treatment is a risk factor for calf mortality.[95] Prophylactic administration of antibiotics to young calves has been associated with an increased incidence of diarrhea[96] and increased calf mortality.[97]

17.6.12 Urogenital System

Neonates on a milk-based diet normally produce large volumes of dilute urine. Normal urine osmolarity in the 2- to 3-day-old calf has been reported to be 286 to 391 mOsm/L, and urine volume voided per day 34 mL/kg/day.[98]

Congenital defects associated with the urogenital system in calves include ovarian aplasia, duplication of the cervix in Hereford cattle, persistence of the hymen (white heifer disease), and rectovaginal constriction in Jersey cattle. Congenital urolithiasis has been described in calves and lambs. Calcium oxalate is the most commonly reported congenital form of urolithiasis and may be associated with other congenital abnormalities.[99] A report of renal oxalosis in a number of Beefmaster calves suggests a possible recessively inherited metabolic defect resulting in primary hyperoxaluria in this breed.[100] Freemartins (XX/XY chimeras) occur in over 90% of bovine[101] and 1% of ovine[102] female heterosexual twins. Typically freemartins are sterile and have hypoplastic ovaries and internal tubal genitalia; the external genitalia normally are not affected. Males should be examined for cryptorchidism and male pseudohermaphroditism, and both sexes for evidence of hermaphroditism (gonads of both sexes).

Rupture of the urinary bladder at parturition is uncommon in ruminants. Clinical signs of a ruptured bladder include dysuria, stranguria, progressive abdominal distention, and depression. A percussion wave may be felt with ballottement of the distended abdomen. Ancillary tests including abdominal ultrasound, abdominocentesis, and assessment of serum and peritoneal electrolytes are useful to verify the diagnosis.

Hemodynamically mediated renal disease is observed sporadically in calves after chronic enteritis.[103] Prolonged reduced renal perfusion secondary to hypovolemia may lead to ischemia and acute tubular necrosis. Failure to thrive after apparent recovery from diarrhea may reflect compromised renal function.

17.6.13 Musculoskeletal System

The musculoskeletal system should be examined for evidence of birth trauma including fractured ribs, long bones, and mandibles, brachial plexus injuries, and soft-tissue trauma including an edematous head and tongue from prolonged compression in the pelvic canal. Strenuous manipulation during a dystocia can also result in Salter-Harris type 1 fractures characterized by disruption of the distal physis in one or more limbs. Femoral nerve paralysis occurs as a sporadic complication of dystocias associated with “hip lock” in calves.[104]

All four legs should be examined for both flexural and angular limb deformities. Although most mild-to-moderate limb deformities correct themselves in a few days, others may need splinting for a successful result. In severe cases of congenital contracture, which are often associated with dystocia, even heroic measures, such as surgical resection of flexor tendons, may provide little or no benefit.

Any heat, swelling, edema, or pain around the joints or physes, or lameness, should be noted. *A swollen joint should be considered infected until proven otherwise*. In older neonates, metabolic bone disease should be considered as a differential diagnosis for lameness associated with flaring of the physis. Diets high in energy and protein that have low calcium and high phosphorus promote rapid weight gain, increasing the physical load on metabolically compromised growing bones. Damage to the growing physis may result in the subsequent development of angular limb deformities. Calcium deficiency in calves leads to reduced mineralization of bone. The transverse processes of the lumbar vertebrae become soft and bend when palpated. Copper deficiency causes metabolic bone disease that is manifested by physitis and brittle bones, reflected by a propensity to develop spontaneous fractures. 278 279

Skeletal muscle myopathy is an important differential diagnosis for lame neonatal ruminants. Lambs and kids with selenium and/or vitamin E deficiency are often mentally bright, are reluctant to stand, and walk with a stiff gait and cry when forced to move. Evaluation of serum creatinine phosphokinase, blood selenium, and plasma vitamin E concentrations is useful to confirm the diagnosis. In regions deficient in selenium, nutritional myodegeneration can be a major cause of death in neonates if the dam was not supplemented with selenium during pregnancy. Nutritional myodegeneration has also been observed when selenium levels are adequate but α-tocopherol levels are low.[105,106] The concentration of vitamin E in sheep colostrum is 5 to 11 times higher than in milk; sheep colostrum appears to be an important source of vitamin E for lambs, as vitamin E is transferred poorly across the placenta. Nutritional myodegeneration secondary to vitamin E deficiency is observed when pregnant ewes are maintained on forage low in vitamin E. Vitamin E–associated nutritional myodegeneration may be prevented by supplementing lambs and kids at birth with α-tocopherol (500 IU orally)* or by supplementing ewes during pregnancy either with a single dose of 500 mg IM 2 weeks before lambing or via dietary supplementation, delivering 150 mg daily for 3 to 4 weeks before lambing.[106] Neonatal nutritional myodegeneration associated with selenium deficiency may similarly be prevented by supplementing neonates at birth (2.5 to 3 mg of selenium per 45 kg) or by supplementing the dam during pregnancy and is discussed further in Chapter 42.

The skull should be examined for excessive doming of the forehead and symmetry. A moderately domed forehead is most commonly the result of intrauterine growth retardation rather than hydrocephalus. The entire vertebral column should be examined for scoliosis, kyphosis, and lordosis and other malformations. Arthrogryposis is characterized by multiple skeletal malformations, including severely contracted limbs and malformations of the vertebrae, and has been associated with the ingestion of toxins, such as locoweed and Sudan grass, by the pregnant mare.[107,108]

Umbilical hernias are the most common congenital malformation. The greatest danger associated with a hernia is strangulation of a portion of the gastrointestinal tract outside the body wall, with compromise of its vasculature. Umbilical hernias in cattle do not tend to close spontaneously and are believed to be hereditary.[109] Dwarfism is a relatively common inherited problem in most cattle breeds. Osteopetrosis has been reported in Angus, Hereford, and Simmental breeds of cattle.[110] Syndactyly is considered an inherited disorder in Holstein-Friesian cattle, and affected animals are also predisposed to hyperthermia.

17.6.14 Neurologic Examination of Neonatal Ruminants

Neurologic disease in neonates during the perinatal period often results from birth asphyxia, congenital disease, or sepsis. Congenital central nervous system (CNS) abnormalities in the large animal neonate may be inherited or may result from in utero infections, toxins, and other environmental factors. Hydrocephalus, hydranencephaly, and anencephaly may occur in calves. In the calf, both Akabane and bluetongue virus may cause hydranencephaly and other problems, including arthrogryposis and premature births. Hydrocephalus is fairly common and appears to be inherited as a simple autosomal recessive trait in many breeds. Internal hydrocephalus may result from a simple recessive gene or congenital BVD infection. Fetal infection with BVD virus may result in a number of other problems, including cerebellar dysplasia, ocular defects, hypomyelinogenesis, and intrauterine growth retardation. Cerebellar hypoplasia may also result from an autosomal recessive gene and is seen in a number of cattle breeds.

Disorders of amino acid metabolism that result in primarily neurologic signs include maple syrup urine disease[111,112] and citrullinemia.[113] Maple syrup urine disease is analogous to branched chain keto acid decarboxylase deficiency and results in clinical signs of extensor spasms, weakness, dullness, recumbency, and opisthotonos shortly after birth. The most striking lesion of the CNS histologically is widespread spongy vacuolation in the white and gray matter of the brain. Citrullinemia, an inborn error of metabolism of the urea cycle, was reported in five neonatal Friesian calves.[113] The calves appeared normal for a short period after birth, but at 24 hours to 5 days of age they developed progressive neurologic signs of depression, tremors, seizures, and opisthotonos, which were followed by death.

Congenital myoclonus (neuraxial edema) is an autosomally recessive inherited disorder of polled Herefords.[114] Clinical signs included premature delivery, inability to stand after birth (with the majority remaining in lateral recumbency), normal mentation, and prominent sensory stimuli-induced myoclonic jerking of the whole body with extension of the head and limbs. The majority of affected animals also display traumatic hip lesions, presumably as a result of the severe myoclonic contractions. Severe alterations in spinal cord glycine-mediated neurotransmission result from a marked decrease or defect in glycine receptors and an increase in neuronal (synaptosomal) glycine uptake. Alterations are also present in the major inhibitory system (γ-aminobutyric acid [GABA] receptors) in the cerebral cortex.[115] Storage diseases in cattle, usually inherited as autosomal recessive genes, include α-mannosidosis in purebred Angus, β-mannosidosis in Salers, GM-1 gangliosidosis in inbred Friesians, neuronal lipodystrophy in Beefmasters, and ‘“shaker calf syndrome” in horned Hereford calves. The last condition was recently recognized as an inheritable neurodegenerative disorder characterized by excessive accumulation of neurofilaments within neurons of the central, peripheral, and autonomic nervous systems. Clinical signs included a normal birth but inability to stand unassisted after delivery. Several hours later the calves developed fine generalized tremors, hyperesthesia to tactile stimulation, weakness, ataxia, and aphonia.[116]

Most acquired neurologic disease in neonates is associated with disease in other organ systems. Sepsis and diarrhea are both commonly associated with depressed mentation secondary to toxemia and/or metabolic derangements. Bacterial meningitis is common in neonates after bacteremia; diarrhea, septic arthritis, omphalophlebitis, and uveitis are frequent concurrent clinical problems. The clinical signs of meningitis in neonates—lethargy, anorexia, and recumbency—are nonspecific. Concurrent metabolic derangements may appear to provide an adequate explanation for the observed depressed mentation. In a retrospective study of 32 cases of bacterial meningitis in calves, concurrent metabolic derangements included hyperkalemia (15/25, 60%), respiratory acidosis (11/24, 46%), hypernatremia (3/20, 15%), and hypoglycemia (3/7, 43%).[117] The more classical clinical signs described for bacterial meningitis in older animals—fever, opisthotonus, extension of the

head, convulsions, hyperesthesia, and signs of neck pain—may not be evident or may not be perceived in neonates. Seizures in calves are often subtle, manifested as facial twitches or jaw champing. Common causes of cerebral disease in lambs and kids include polioencephalomalacia and focal symmetric encephalomalacia. Affected animals are typically depressed and blind but have normal pupillary light reflexes. 280

Posterior paresis is common in neonates; causes include border disease, enzootic ataxia, vertebral body abscesses, caprine arthritis encephalomyelitis virus, and vertebral body fractures associated with dietary copper deficiency or calcium phosphorous imbalance. These neurologic problems are discussed in Chapter 35.

18 Chapter 18 Neonatal Infection

Wendy E. Vaala

John K. House

Guy D. Lester

Infection, both generalized and localized, is an important cause of morbidity and mortality in the large animal neonate; in both calves and foals, bacteria cause most infections. The prognosis of neonatal infection varies considerably depending on the type and severity of infection. The traditional view of sepsis includes a pivotal role for bacterial endotoxins with resultant overactivation of the host immune system and release of endogenous proinflammatory and antiinflammatory mediators. This response could then precipitate a cascade of metabolic and hemodynamic changes that may culminate in multiple organ system failure.[1,2] This traditional model of sepsis has recently been challenged with a decreased emphasis on a primary role of bacterial endotoxins and a new focus on the regulation of Toll-like receptors (TLRs) in generation of the systemic inflammatory response syndrome (SIRS) and the sepsis syndrome.[3] It has been suggested that TLR4, the putative endotoxin receptor, is under a constant state of inhibition. Endogenous factors generated in response to tissue inflammation lead to release of TLRs from inhibition as well as acting as TLR agonists. TLR activation results in a potent proinflammatory response. This model provides a common pathway of SIRS, irrespective of initiating causes (e.g., gram-negative bacteria, gram-positive bacteria, tissue trauma, neoplasia). Although further refinement is needed for acceptance of this model of sepsis, it may provide the window for novel therapies in the prevention and treatment of sepsis.

Much of the information related to sepsis and endotoxemia in horses has been derived from experimental endotoxin bolus or infusion in healthy animals. Endotoxin activates cytokine-mediated procoagulant effects on endothelial cells.[4] The initial response to endotoxin is activation of coagulation.[5] As the inflammatory response progresses, systemic hypercoagulability may progress to hypocoagulability, with fulminant signs of hemorrhage recognized as disseminated intravascular coagulation (DIC).[4] Circulatory failure, perfusion deficits, and an inability of the body to use existing metabolic substrate effectively characterize septic shock, the end point of that continuum. If the neonate survives acute sepsis, localized areas of infection such as pneumonia, uveitis, synovitis, physitis, meningitis, hepatitis, and enteritis may then appear. In the past decade, survival rates of septicemic foals have improved considerably because of advances in early detection procedures and critical care management techniques,[6–11] but it is far preferable to prevent[12] septicemia by using good management techniques and by ensuring that the newborn acquires good colostrally derived immunity. The prognosis for septicemic neonates admitted for treatment in the late stages of the disease remains poor because bacteria are usually already well established in many organs, particularly the bones and joints. In these cases, even if the neonate survives on a short-term basis, a number of chronic complications result in an unfavorable long-term outcome. Foals with adequate transfer of maternal immunoglobulins can still succumb to generalized infection after birth, but animals with partial or total failure of passive transfer (FPT) have a greater risk of morbidity or mortality resulting from infection.[13] See Chapter 53 for details on the detection, prevention, and treatment of FPT.

18.1 ETIOLOGY AND NEONATAL IMMUNITY

Most neonatal infections are caused by opportunistic bacteria that normally live in the genital tract, on the skin, or in the environment of normal horses, cows, sheep, and goats. Infection may be acquired prenatally, through the placenta, from the birth canal, or from the environment after birth. Portals of entry include the respiratory and

gastrointestinal tracts, the placenta, and the umbilicus. A number of abnormalities in the late gestation mare make infection more likely in the neonate (see Chapter 15). Bacterial placentitis is a common cause of premature delivery and infection in the newborn foal; most cases result from ascending infection through the cervix. Perinatal stress, including chronic in utero hypoxia, prematurity, dystocia, and birth asphyxia, renders the neonate more susceptible to infection. Unsanitary environmental conditions, overcrowding, poor ventilation, contamination of the environment with pathogenic bacteria such as *Salmonella* species,[12] and other poor management techniques also predispose to infection.[9]

The propensity for contagious and opportunistic infections in neonates reflects the immature status of their immune system. At birth, foals, calves, lambs, and kids are hypogammaglobulinemic or agammaglobulinemic and immunologically naive. Bovine colostrum contains approximately 45 mg/mL[14] of immunoglobulin and 10^6 leukocytes/mL.[15] Passively derived immunoglobulins enhance neonatal immunity by functioning as neutralizers and opsonins. The association between FPT of immunoglobulins and neonatal infection has been well established in the calf[16,17] and suggested by several studies in the foal.[13,18–20] Colostral leukocytes participate in regulation of the neonate's immune response. Comparison of the immune response of calves fed leukocyte-replete or leukocyte-depleted colostrum indicates that colostral leukocytes enhance humoral immunity and phagocyte function.[21–25] After experimental *Escherichia coli* infection, calves fed leukocyte-replete colostrum recovered more quickly and shed fewer bacteria than calves fed leukocyte-depleted colostrum.[15] Transfer of cellular immunity via colostral leukocytes has also been demonstrated in sheep.[26] Colostral leukocytes are destroyed when colostrum is frozen, pasteurized, or fermented.

The phagocytic and bacterial killing function of neutrophils (polymorphonuclear neutrophils [PMNs]) is a crucial component of the primary immune response against invading pathogens. Despite a larger number of neutrophils in the circulation of normal calves at birth, neutrophils from neonatal calves are functionally less effective than adult cells. Reduced Fc receptor expression in neonatal PMNs may contribute to impaired phagocytosis and antibody-dependent cellular cytotoxicity.[27–29] Depressed PMN bacterial killing[30] may be related to reduced superoxide anion[31] and myeloperoxidase—hydrogen peroxide—halide antibacterial activity.[29] Adult level superoxide activity in fetal PMNs suggests that some of the deficits in neonatal PMN function may be a manifestation of perinatal PMN suppression.[32] Calves have elevated cortisol levels for the first 10 days of life, which may contribute to depression of neutrophil function.[33] Dexamethasone depresses neutrophil phagocytosis, antibody-dependent cellular cytotoxicity, and bacterial killing.[34,35] Undefined serum factors also appear to be important for PMN function, as phagocytosis and bacterial killing by neonatal PMNs is similar to that of adult PMNs when bacteria are opsonized with adult serum but is reduced when bacteria are opsonized with neonatal serum.[30] T helper cells ($CD4^+$) play a central role in humoral and cell-mediated immunologic memory. Lymphokines produced by $CD4^+$ cells, interleukin (IL)-2, IL-4, and interferon gamma (IFN-γ) are essential components of antigen-specific immunity. Virtually all IL-4 and most IFN-γ produced by polyclonally activated adult human $CD4^+$ cells are mediated by a subset of "functional memory cells."[36] Leukocyte production of IL-4 and IFN-γ is reduced in human neonates,[36] and IFN-γ in bovine neonates,[*] possibly reflecting their antigenically naive status. Depressed lymphocyte proliferation and IL-2 activity in the perinatal period correlates with elevated cortisol levels.[33]

281

282

Acquisition of humoral immune competence is age and antigen dependent.[37] Neonates are capable of producing humoral immune responses to good immunogens (protein antigens) but may fail to respond to lesser immunogens (sugars and lipids). Calves less than 3 months of age vaccinated with modified live or killed salmonella vaccines produce an adult-type humoral immune response to salmonella protein antigens but do not respond to salmonella

lipopolysaccharide (LPS).[38] Ingestion of colostrum suppresses the humoral response to some antigens but not to others.[37]

Adverse management and environmental conditions further compromise neonatal immunity. Cold stress depresses neutrophil chemotaxis, and vasoconstriction reduces delivery of leukocytes to peripheral tissues.[39] Protein energy malnutrition in calves is associated with depressed lymphocyte IL-2 activity, lymphocyte proliferation, and humoral immune responses.[33] Micronutrient deficiencies also depress immunity. Selenium, zinc, copper, and vitamin E deficiencies depress lymphocyte and phagocyte function.[40,41]

Inherited defects in immune function are sporadically observed in neonates and should be considered when recurrent or atypical infections are observed—for example, *Pneumocystis carinii* pneumonia in foals. Inherited immunodeficiencies are discussed in Chapter 53.

18.2 PATHOGENESIS OF SEPSIS

As discussed earlier, the pathogenesis of sepsis is yet to be fully elucidated.[3] Systemic sepsis can be caused by a range of infectious agents including gram-positive bacteria, gram-negative bacteria, fungi, and viruses. Interaction between viruses, bacteria, or bacterial products and TLRs appears pivotal in the induction of the proinflammatory and antiinflammatory responses.[42] Endotoxin is a mediator of gram-negative sepsis. Endotoxin, the LPS component in the outer cell membrane of gram-negative bacteria, is released whenever the bacterial cell membrane is disrupted, as occurs during rapid growth or cell death. Endotoxin is composed of hydrophilic heteropolysaccharide and hydrophobic lipid. The surface portion of LPS is the O-antigenic determinant consisting of sugar chains that are highly variable among species. Deeper within the LPS molecule is the lipid moiety, which is responsible for most of the endotoxin's biologic activities. Binding of LPS to TLR4 receptors leads to expression of nuclear factor—kappa B (NF-κB)–controlled proinflammatory cytokines and IFN-regulatory factors and type I IFNs.[42] The reticuloendothelial system is responsible for detoxification of endotoxin. Gram-positive bacteria do not produce endotoxin but elaborate lipoteichoic acid and peptidoglycan, which can effect a similar inflammatory response through activation of other TLR receptors, TLR2 and TLR6.[42]

The initiating event in the generalized bacterial sepsis syndrome is the presence of bacteria and/or bacterial products within the circulation. Subsequent binding with surface TLRs and other immune system components triggers intracellular signaling pathways that activate the genes and enzymes responsible for production and maturation of cytokines and IFNs. Proinflammatory products include the cytokines tumor necrosis factor alpha (TNF-α), IL-1, IL-6, transforming growth factor (TGF)–β, and IFN-γ. Antiinflammatory cytokines include IL-4, IL-10, and IL-13. The cascade yields other products including kinins, myocardial depressant factor, β-endorphins, free-radical oxygen species, lysosomal enzymes, and prostaglandins.[1,2,43] Serum TNF concentration has been correlated with clinical criteria of sepsis in calves and foals.[44,45] Many of the inflammatory mediators have direct effects on the vascular endothelium, resulting in increased endothelial permeability. The endothelium also releases two additional substances: endothelium-derived relaxing factor (EDRF), and endothelin-1. EDRF has been identified as nitric oxide (NO) and is responsible for relaxing smooth muscle, depressing myocardial function, decreasing vasopressor responsiveness, and inhibiting platelet aggregation.[46,47] Endothelin-1 is a potent vasoconstrictor. After the increase in vascular permeability, interstitial and pulmonary edema, hypovolemia, and decreased cardiac output develop. Pulmonary and systemic hypotension develops. Splanchnic perfusion decreases,

and coagulation pathways are activated, resulting in varying degrees of DIC. The majority of patients that die of septic shock suffer multiple organ failure.[2]

Respiratory failure is a frequent complication of septic shock. As pulmonary capillary permeability increases, leukocytes accumulate and degranulate in the pulmonary microvasculature, resulting in endothelial damage, increased capillary leakiness, and alveolar flooding. Lung collapse (atelectasis), intrapulmonary shunting, and mismatching of ventilation and perfusion develop. Terminally, hypoxemia, pulmonary hypertension, progressive lung collapse, pulmonary edema, and respiratory failure develop.[2]

Myocardial depression occurs during sepsis. Endotoxin and NO exert a direct inotropic depressant effect on the heart. During early sepsis stimulation of the sympathetic nervous system results in tachycardia, increased cardiac output, improved myocardial contractility, and increased oxygen consumption. As sepsis progresses, there is a decrease in vascular tone and oxygen extraction by peripheral tissues, accompanied by development of metabolic acidosis and anaerobic metabolism. During late sepsis, myocardial failure develops, accompanied by decreased cardiac output and severe hypotension. A recent study reported elevations in the cardiac biomarkers cardiac troponin I and creatine kinase MB in septic foals compared with healthy neonatal foals.[48] The magnitude of either of these markers did not predict outcome.

282

283

Sepsis is best characterized nutritionally by hypermetabolism, catabolism, and protein wasting.[49] During sepsis, intermediary metabolism is disrupted and the foal loses sequentially the ability to use glucose, then fat, and finally protein as energy sources. Elevated concentrations of catecholamines and glucagon contribute to insulin resistance and increased lipolysis. These changes explain the hyperglycemia and lipemic serum occasionally observed in foals with sepsis.

18.3 INFECTIOUS AGENTS ASSOCIATED WITH NEONATAL DISEASE

In all studies conducted in the United States, Europe, and Australia in the past 20 years, gram-negative bacteria have been the predominant cause of infection in large animal neonates, and *E. coli* has been by far the most common bacterial species isolated.[6,7,9,10,50–55] Other common bacterial organisms include *Actinobacillus* species (foals), *Pasteurella* species (calves and foals[56] [rare]), *Klebsiella* species, *Salmonella* species (calves and foals), and less commonly *Pseudomonas* species, *Listeria monocytogenes,*[57] *Clostridium perfringens* and *Clostridium septicum,*[58] *Staphylococcus aureus,* and *Streptococcus* species. Although *Streptococcus* species are most commonly isolated in mixed infections with gram-negative bacteria,[6,7] both alpha- and beta-hemolytic *Streptococcus* species have been isolated in pure culture in foals with large subcutaneous abscesses and physitis and septic arthritis. *Streptococcus pneumoniae* type 3, typically a human pathogen, was identified as the cause of severe respiratory distress in a neonatal foal.[59] Polymicrobial infections are common in calves with septicemia (28%).[52] Surveys examining blood culture results of foals admitted to neonatal intensive care units reflect a trend in the type of bacterial organisms contributing to septicemia. There has been an increase in the number of gram-positive bacterial isolates including *Streptococcus* (alpha and beta) species, *Staphylococcus* species, *Enterococcus* species, and *Clostridium* species.[60] These statistics serve to remind clinicians not to ignore the pathologic significance of gram-positive organisms when selecting an antibiotic regimen for the septic neonate. Although newer antibiotics including some of the cephalosporins, β-lactam antibiotics, and fluoroquinolones have an extended gram-negative spectrum, their gram-positive spectrum may be inadequate for pathogens such as *Streptococcus* species.

Most organisms known to cause placental and fetal disease may cause disease of the newborn. Infectious agents associated with abortion, stillbirths, and birth of weak ruminant neonates are listed in Box 15-3. Infections of neonates contracted in utero are uncommon compared with postnatally acquired infections. Clinical signs of in utero infections are dependent on the age of the fetus at the time of infection and the tissue tropism and virulence of the infecting organism. Abortion storms and outbreaks of perinatal weakness, congenital defects, and mortality are often manifestations of widespread herd or flock infections. Subclinically infected neonates may remain chronically infected, providing a continuing reservoir of infection in the population. Transplacental infection is important in the epidemiology of a number of diseases including Johne's disease *(Mycobacterium paratuberculosis),* bovine virus diarrhea, and bovine leukosis.[61–63]

Although viral agents are most commonly associated with abortion in the mare, viral infections may also occasionally cause disease in the newborn foal. Equine herpes viral infection may result in a weak newborn foal that responds very poorly to conventional supportive care; antemortem diagnosis is very difficult.[64,65] Equine viral arteritis has been reported in neonatal foals.[66,67] Equine influenza may be associated with interstitial pneumonia in foals.[68]

Fungal infections have been observed in neonatal foals. The development of severe, generalized candidiasis has been observed in debilitated or immunocompromised foals undergoing intensive care. A history of prolonged antimicrobial use is common. Diagnosis has been made using blood cultures or cultures of joint aspirates.

18.4 CLINICAL SIGNS

The spectrum of clinical signs associated with septicemia depends on the integrity of the host immune system, the duration of illness, the severity, the route of infection, and the target organs. Early in the clinical course, the clinical signs are usually nonexistent or vague, nonspecific, and easily attributed to other diseases. During the early hyperdynamic phase of sepsis, clinical signs include lethargy, hypotonia, more time spent sleeping, decreased nursing frequency followed by complete loss of suckle reflex, hyperemic mucous membranes with rapid capillary refill time associated with peripheral vasodilation and increased cardiac output, tachycardia, bounding peripheral pulses, extremities that are still warm, tachypnea, and variable body temperature. Capillary leakiness contributes to the early appearance of petechiae on the gums, sclera, inside of the ears, and coronary bands. As soon as the foal's nursing vigor decreases, the mare's udder becomes warm and distended and may stream milk spontaneously. When the weak foal does nurse from the overdistended udder, it often comes away with a milk-stained face owing to the spontaneous milk letdown that it is too weak too swallow. Dehydration develops rapidly, resulting in decreased urine output and constipation. Obviously, the earlier the infection is diagnosed, the better chance the treatment has of being successful. Localizing signs may or may not be present. Prompt and aggressive intervention at this stage of the disease process frequently results in a successful outcome.

During late sepsis, when infection overwhelms the host's immune system, septic shock develops. Affected foals are usually recumbent, dehydrated, and almost moribund. Clinical signs include severe hypotension associated with hypovolemia and decreased cardiac output, tachycardia, altered mentation, cold extremities, weak peripheral pulses, and dry, injected mucous membranes with a toxic ring and prolonged capillary refill time. Hypothermia is common. Gut motility is usually decreased and is accompanied by gastric reflux, abdominal distention, and constipation or diarrhea. Colic may be present if the ileus and abdominal distention are severe. Liver dysfunction is associated with cholestasis and increasing clinical jaundice. Decreased pulmonary perfusion and increased vascular permeability contribute to progressive respiratory compromise. Signs of respiratory distress include tachypnea, dyspnea with nostril flare, rib retractions, and expiratory grunting. Salvage of the patient in late septic shock is

usually not successful. Although an encouraging response to intensive therapy may be noted initially, most neonates presented in late septic shock do not survive.

Fever is inconsistently present in infected foals; the possibility of infection should never be ruled out because of the absence of fever.[6] Foals in septic shock often have a subnormal rectal temperature. In one study diarrhea was the most common early localizing sign in a group of foals with septicemia.[6] The pathophysiologic basis of the diarrhea is not known but may relate to altered intestinal perfusion. *E. coli* is the common cause of systemic sepsis in foals, but it is a rare cause of primary enteric disease. Other signs include seizures (with or without the presence of meningitis or encephalitis), colic, respiratory distress, uveitis, subcutaneous abscesses, joint distention and/or periarticular edema, and umbilical abscessation. The signs of osteomyelitis or physeal infection may be extremely subtle, with no obvious areas of inflammation detectable on the limbs. The only clues may be a reluctance to move, a choppy, stilted gait, and/or an inflammatory hemogram (increased fibrinogen, in particular).

283
284

The time of onset of clinical signs of infection in the neonate depends on whether the infection was acquired in utero or postnatally. Animals infected in utero generally begin to show signs sometime during the first 24 hours of life, whereas postnatally infected animals often appear relatively normal for the first 2 days of life or longer. *Actinobacillus* infections in foals may become apparent somewhat earlier (24 to 48 hours of age) and are commonly characterized by an acute onset of depression, diarrhea, or rapidly distending, painful joint(s). Bone and joint infections in neonates may not be obvious for several days to weeks, and their appearance may either follow an improvement in systemic signs of illness or not be accompanied by any signs of systemic illness.

As with foals, septicemia in ruminant neonates commonly involves multiple organs with the respiratory and gastrointestinal systems most commonly affected.[52] Clinical signs are often nonspecific and may include lethargy, poor suckle reflex, weakness, dehydration, tachycardia, tachypnea, and recumbency. Findings suggestive of involvement of a particular organ system include diarrhea, lameness, omphalophlebitis, neurologic and ocular signs, and cardiac murmurs. Depressed mentation, diarrhea, and dehydration are the most common clinical signs of sepsis in neonatal ruminants, but clinical presentation is variable.[54] Rectal temperature, heart rate, and respiratory rate are poor predictors of sepsis in calves.[54,55] Fecteau and co-workers have developed a clinical score model for predicting sepsis in calves to promote rational antimicrobial use by producers.[55] Criteria included in the model include fecal consistency, hydration status, attitude (mental awareness), and umbilical and scleral vessel assessment. Sensitivity and specificity of the model were 76% and 75%, respectively. In the calves examined by Fecteau and colleagues the presence of severe diarrhea or a localized infection (e.g., infected navel) was associated with an increased probability of bacteremia as determined by blood culture.

18.5 DIAGNOSIS OF BACTERIAL INFECTION IN NEONATES

It is not difficult to diagnose an infected neonate when overwhelming sepsis is present. Bacteria may be observed on a peripheral blood smear in cases of advanced sepsis. Unfortunately, if treatment is instituted at this time, it is unlikely to be successful. Because of the necessity of early diagnosis and treatment of infection for a favorable outcome, a reliable, rapidly available field test to establish the presence of infection would be highly desirable. Such a test is not currently available. Positive blood cultures are the only definitive antemortem proof of bacteremia, but a minimum of 24 hours is usually required for preliminary results.

Because of the difficulty in identifying early sepsis at a treatable stage, a scoring system has been developed for the neonatal foal that incorporates a group of historic parameters, physical examination findings, and laboratory values, which together have been found to be considerably more accurate than any one single parameter in establishing the likelihood of infection.[69] The sepsis score is intended for use as a diagnostic aid only and is not 100% accurate.

False-negative results occur in older foals, and false-positive results are common in foals born prematurely. If the score is low for an individual foal but clinical suspicion of infection is high, antibiotic therapy should be instituted, and further assessment should then be performed.

The white blood cell (WBC) count and differential are important parts of the sepsis score. A number of foals in the early stages of septicemia have a normal total WBC count, but most have either an increased number of immature (band) neutrophils (>50 cells/μL) or toxic changes (Döhle bodies, toxic granulation, vacuolization) in the neutrophils. Foals that die of septicemia generally have very low WBC counts with considerable toxicity, but a low WBC count in a patient with sepsis does not necessarily predict death. The WBC count may undergo dramatic changes in a short period of time, often preceding changes in clinical condition. Foals with infection acquired in utero as a consequence of bacterial placentitis typically are born with elevated WBC counts. There is some evidence that very high WBC counts are positively correlated with successful outcomes. The fibrinogen concentration is also useful in detecting newborn foals that have been infected or exposed to inflammatory placental disease in utero. Fibrinogen values in these cases may be 1000 mg/dL or greater at birth (normal is 300 mg/dL or less), and, again, high values are often positively related to outcome. In the early stages of postnatally acquired infections, fibrinogen values may be only mildly increased (400 to 500 mg/dL), but with increasing chronicity resulting from pneumonia or bone and joint infections, plasma fibrinogen levels may increase dramatically.

Total plasma protein concentration is highly variable and may be influenced by dehydration, catabolism, and ingestion of colostral immunoglobulins. The range of presuckle protein concentration varies so much between foals that it is not a reliable indicator of FPT. IgG determination has been shown to be an important component of the sepsis evaluation, in that low IgG levels have strongly correlated with the presence of sepsis. Severe, overwhelming infections are seen far less commonly in foals with normal immunoglobulin G (IgG) levels (>800 mg/dL) but can occur, particularly in individuals with in utero acquired infections and severe enteric infections caused by pathogenic bacteria such as *Salmonella* species and clostridial intestinal infections. Because serum IgG levels can change dramatically as a result of protein catabolism associated with sepsis, it is often difficult to determine whether hypogammaglobulinemia in a sick foal is the cause or result of sepsis.

Hypoglycemia (glucose <60 mg/dL; <3.3 mmol/L) commonly accompanies generalized infection and is associated with bacterial consumption and reduced glycogen reserves. Serum glucose values can be very low, with the animal showing few signs other than depression and weakness.

The potential application of hematologic evaluation of neonates for early detection of sepsis is illustrated in a study reported by Adams and colleagues.[70] Hematologic values in 35 newborn beef calves were evaluated; five calves subsequently developed clinical signs of sepsis at 3 weeks of age. Comparison of hematologic values from the five diseased calves with values for healthy calves revealed significant differences at each sample collection time (birth, 24 hours, 48 hours, and 3 weeks), although disease was not clinically evident at the three early sample times. 284
Compared 285 with the clinically normal calves the five septic calves had more band neutrophils and a higher neutrophil-to-lymphocyte ratio at birth. At 24 hours the monocyte count was higher, and at 48 hours total leukocyte, mature neutrophil, and monocyte counts and neutrophil-to-lymphocyte ratio were higher in the five calves. At 3 weeks, when clinical signs of disease were detectable in the five calves, the total leukocyte, band neutrophil, and mature neutrophil counts, neutrophil-to-lymphocyte ratio, and plasma total protein and fibrinogen concentrations were higher.[70]

Hematologic abnormalities observed in septic calves with clinical signs of disease are not consistent. In a retrospective study of 25 septic calves a noticeable feature of the pattern of laboratory abnormalities was the contrast of severe clinical signs with minor complete blood count (CBC) and serum biochemical alterations in

numerous calves.[52] Abnormal laboratory findings included neutrophilia or neutropenia, immature neutrophils, toxic neutrophils, and hyperfibrinogenemia.[52] Low serum immunoglobulin concentrations are also commonly observed in calves with sepsis.[52,55] The most common abnormalities observed in calves with DIC include activated partial thromboplastin time (aPTT) and prothrombin time (PT), observation of schistocytes, and elevated fibrin degradation products. Thrombocytopenia is less frequently observed.[71] Abnormalities of the coagulation and the fibrinolytic systems are also common in neonatal foals with sepsis.[72] Prolongation of PT and aPTT are common, as are increased concentrations of fibrin degradation products.[73] Foals with advanced sepsis may show signs of spontaneous hemorrhage or vascular thrombosis.

Lactate measurement is an important indicator of foal sepsis and if taken at admission may provide important prognostic information.[74] Lactate is normally <2.5 mmol/L; levels between 2.5 and 5 mmol/L are typically not associated with acidosis, whereas values<5 mmol/L are often associated with acidosis. Substantial reductions in blood lactate in response to 24 hours of therapy often translate into a favorable outcome.[75] Other abnormal serum chemistries associated with sepsis include metabolic acidosis (bicarbonate <19 mEq/L) resulting from increased anaerobic metabolism and azotemia (creatinine <2 mg/dL) secondary to dehydration as well as primary renal damage. During the terminal stages of septicemia, foals frequently display a mixed respiratory and metabolic acidosis accompanied by hypoxemia. Lipemia and hyperbilirubinemia reflect altered endocrine and hepatic function.

Positive blood cultures are essential to make the diagnosis of septicemia. However, it is clear that treatment cannot be delayed until results of blood cultures are obtained. Although it does not help to make the initial decision regarding therapy, a positive blood culture allows a more accurate prognosis to be given to the owner, provides information about the type of bacteria and its susceptibility pattern, and helps guide the decision as to length of antibiotic treatment.

Blood cultures are easy to perform but must be done carefully for accurate results. The hair should be shaved, and the site of venipuncture surgically scrubbed. Depending on the type of culture bottle or tube, a set amount of blood is withdrawn from the vein aseptically and deposited into both anaerobic and aerobic blood culture bottles. A liquid or solid blood culture medium can be used. One popular culture medium is Columbia broth medium with sodium polyanetholsulfonate as anticoagulant for aerobic cultures (Septi-Chek, Roche Laboratories, Nutley, NJ) and a brain-heart infusion medium for anaerobic cultures. If the medium is not readily available, the sample can be transferred in a yellow-top tube containing anticoagulant citrate dextrose (ACD). Serial cultures are preferred. A clean needle is used for transferring the blood into each bottle. The bottles are then incubated. A positive culture is characterized by marked turbidity, usually within 12 to 48 hours of incubation. The medium with bacterial growth is then Gram stained and plated out for identification and susceptibility testing. Working with a local human hospital may provide the ideal resource when trying to identify bacteria and establish antibiotic susceptibility patterns.

Other samples that can be used for culture in addition to urine and blood are synovial fluid, cerebrospinal fluid (CSF), peritoneal fluid, feces, and transtracheal aspirate. In cases of physeal osteomyelitis a physeal aspirate may be beneficial.

Many referral hospitals perform blood culture on all abnormal neonatal foals on admission, whether or not they received antibiotics previously, and the foals should then be placed on antibiotics if infection is suspected. Bacterial cultures are also taken from specific areas if local infections are suspected (CSF, joint, feces, trachea). With only one blood culture routinely taken per foal, some false-negative results have been obtained, but the number of positive results has been surprising.[6,51] However, foals with in utero—acquired pneumonia have rarely had positive

results on blood culture, and additional culture specimens (e.g., tracheal aspirate) should also be taken. If a fever spike occurs during the hospital stay, if the WBC count changes dramatically, or if the clinical condition of an infected foal deteriorates, the blood is recultured. The development of resistant infections has been observed in both community- and hospital-acquired infections, and their prompt detection is very important.

18.6 THERAPY FOR BACTERIAL INFECTION

Antibiotic therapy is currently the cornerstone of treatment of neonatal infection. Because sepsis can progress with devastating speed in the neonate, antibiotic therapy should be started as soon as sepsis is suspected. Broad-spectrum coverage should be initiated pending culture results, anticipating the preponderance of gram-negative bacteremia, the reemergence of gram-positive pathogens, and the possibility of polymicrobial infections. Bactericidal drugs are favored for treatment of sepsis in neonates because of the immaturity of the neonatal immune system. Immaturity of mechanisms involved in drug absorption, distribution, biotransformation, and excretion contribute to altered pharmacokinetics of antimicrobials in neonates. Implications of altered pharmacokinetics in neonates include the potential for suboptimal therapeutic concentrations, toxic effects, and, of importance in food animals, violative residues if adult dosing regimens are employed. In general terms, antimicrobials have longer elimination times in neonates (less than 2 weeks of age) than in adults and therefore larger doses are administered with a longer dosage interval to achieve similar peak and trough antimicrobial concentrations. More complete discussions of antibiotic therapy in neonatal foals[10,76,77] and food animals can be found in other texts.[78–81] The use of immediate antimicrobial therapy in advanced cases of sepsis is controversial. It has been suggested that lysis of circulating bacteria could further contribute to endotoxin load, hastening circulatory collapse and death. In vitro data indicate that β-lactam antibiotics, such as ceftiofur or ampicillin, but not aminoglycosides, may lead to an increase in endotoxin concentration.[82]

The duration of antibiotic therapy in infected neonates depends on the clinical status of the patient and what type of infection has been documented. One week to 10 days of therapy may be adequate for suspected but undocumented sepsis if the CBC, fibrinogen, and patient are normal at the end of therapy. A minimum of 2 weeks of treatment is suggested in blood culture—positive patients with no evidence of localized infections. Three to 4 weeks (or more) of antibiotic treatment are often required when the infection has localized, particularly in the joints or lungs. Therapy is usually discontinued when the WBC count, fibrinogen, and radiographs have returned to normal. Although there has been concern about the use of aminoglycoside antibiotics in the neonatal foal, the well-hydrated neonatal foal tolerates these drugs very well, even after extended periods of treatment (2 to 4 weeks).

285

286

Established sepsis in the neonate carries a poor prognosis, with less than 12% survival of calves with sepsis in a referral hospital.[52] Client education to facilitate early recognition and treatment of neonates with sepsis improves outcome and reduces cost.

18.6.1 Antimicrobial Therapy in Foals

The combination of a penicillin and an aminoglycoside, such as gentamicin (6.6 mg/kg given intravenously [IV] or intramuscularly [IM] once per day [sid]) or amikacin (21 to 25 mg/kg IV or IM, sid), provides good antimicrobial coverage. Some clinicians have used gentamicin at 6.6 mg/kg twice per day (bid) as long as in-hospital monitoring is available. Amikacin is often preferred to gentamicin because it seems to be less nephrotoxic and less likely to be associated with the development of resistant bacterial infections.[10,77,83] Ideally, peak and trough serum aminoglycoside concentrations are monitored to ensure that the proper dose and dosing interval are used, but this is not often possible in a field setting. Unfortunately, no studies have been conducted in the foal to determine the specific peak and trough serum concentrations resulting in optimal survival rates in

individuals with sepsis.[84] Based on work in other species a target peak concentration of 15 to 30 µg/mL and trough concentration of 1 to 3 µg/mL have been suggested.[85] During long-term aminoglycoside therapy, efforts are made to prevent dehydration, and the patient's urinalysis and serum creatinine are monitored at least weekly.

Other antibiotics that may be useful in the empirical treatment of the infected neonate include certain third-generation cephalosporins, such as ceftiofur (2.2 to 4.4 mg/kg IV or IM bid), cefotaxime (20 to 30 mg/kg IV or IM three times per day [tid]), ceftriaxone, and ceftazidime. In studies of susceptibility patterns of bacteria cultured from foals undergoing treatment in intensive care units, antibiotics such as ampicillin, kanamycin, and tetracycline were of very little value for treatment of gram-negative infections. Twenty percent to 40% of isolates were resistant to trimethoprim-sulfonamide (TMS) combinations (15 mg/kg bid IV, orally [PO]), ceftiofur (2.2 to 6.6 mg/kg IM bid), chloramphenicol (25 to 50 mg/kg IV or PO four times per day [qid]), and ticarcillin-clavulanate (50 mg/kg IV, tid or qid).[7,9,51,86] Some, however, have reported success with tetracyclines in the management of osseous infection. A susceptibility pattern should document that the organism is indeed susceptible before these antibiotics are selected for use. Fluconazole may be effective in treatment of localized and generalized candidiasis. One recommended dosage for foals is a loading dose of 400 mg followed by 200 mg at 24-hour dosing intervals.[10]Q See Chapter 45 for further discussion of antibiotics.

18.6.2 Antimicrobial Therapy in Neonatal Ruminants

Common medical conditions in neonatal calves that require antimicrobial therapy include diarrhea, pneumonia, bacteremia, omphalophlebitis, osteomyelitis, meningitis, and septic arthritis.

Bacteremia is a common problem in debilitated neonatal ruminants. Rapid recognition and treatment of sepsis improves the likelihood of a successful outcome. Blood culture studies of debilitated calves indicate that gram-negative bacteria account for approximately 80% of bacterial isolates; *E. coli* is the most common species of bacteria isolated.[52,54,87] In a study of 190 recumbent calves on a large calf-raising facility, 31% were determined to have bacteremia. *E. coli* accounted for 51% of the isolates; other gram-negatives, 25%; gram-negative anaerobes, 5.9%; gram-positive cocci, 11.8%; and gram-positive rods, 5.9%.[87] Empiric antimicrobial therapy should include a gram-negative and gram-positive spectrum. Other considerations pertinent to antimicrobial selection include the pharmacokinetics and pharmacodynamics of the drug in neonates, likelihood of antimicrobial resistance, and potential for violative antimicrobial tissue residues. Determination of antimicrobial susceptibility (minimal inhibitory concentration [MIC]) before therapy is desirable but often not possible. Alternatively, a drug may be selected and given at a dosage that has been shown to be effective for ≥90% of similar isolates tested (MIC 90%). The objective of measuring antimicrobial MIC' is to facilitate antimicrobial selection that is likely to achieve a therapeutic concentration of drug for the target pathogen. The MIC data are of limited value without information on serum and tissue concentrations attainable using the intended drug dose. Data regarding microbial susceptibility to antimicrobial drugs are provided in Table 18-1, and pharmacologic data regarding the volume of distribution, half life, and breakpoint MICs of common antimicrobial drugs are presented in Table 18-2. The data presented in the tables are intended as a guide. Being from different studies, they reflect the magnitude of differences that may be observed over time and among sources. The data reflect intravenous administration. The half-life of drugs is often longer after intramuscular injection, reflecting absorption rate—dependent elimination.[114]

Vd, Volume of distribution.

Antimicrobial drugs with a gram-negative spectrum of activity include third-generation cephalosporins (ceftiofur), TMS, fluoroquinolones (enrofloxacin), aminoglycosides, sulfonamides, and tetracyclines. Although florfenicol has a gram-negative spectrum, the MIC90 for *E. coli* is very high at 25 mg/mL.[88] Intramuscular injection of florfenicol (20 mg/kg IM) fails to reach the MIC90 value in plasma, and intravenous injection (11 to

20 mg/kg IV) exceeds the MIC90 value for only 60 minutes.[89–91] The National Cattlemen's Association (NCA) recommends that “until further scientific information becomes available alleviating safety and efficacy concerns, aminoglycoside antibiotics should not be used in cattle except as specifically approved by the FDA” (*Herd Health Memo,* No. 9, p. 82, 1993–1994). The bacteriostatic action and frequency of antimicrobial resistance to tetracyclines and nonpotentiated sulfonamides limits their effectiveness in neonates with sepsis. TMS may be used to treat sepsis in neonatal calves, but its half-life rapidly declines as ruminal function develops. In ruminating (6- to 8-week-old) calves, subcutaneous or oral administration of TMS leads to high serum levels of sulfadiazine but little or no serum trimethoprim.[92] Bacterial resistance to TMS is less common than resistance to sulfa drugs alone but still may be high.[54,93] Fluoroquinolones such as enrofloxacin are bacteriocidal and have an appropriate gram-negative spectrum of activity suitable for treatment of gram-negative sepsis. *However, in the United States, enrofloxacin is conditionally licensed for treatment of respiratory disease in beef cattle*. In countries where it is legal to use enrofloxacin for treatment of neonatal sepsis, a dosage rate of 2.5 to 5 mg/kg every 24 hours has been suggested as appropriate for calves.[94] Enrofloxacin has demonstrated good efficacy in the treatment of *E. coli* septicemia, *Salmonella* enteritis, and *Mycoplasma* and *Pasteurella* pneumonia in calves.[95–97] Prolonged administration of enrofloxacin (weeks) is not recommended, as it produces articular erosions in immature animals of other species. Ceftiofur has an appropriate antimicrobial spectrum, is bacteriocidal, and has been used to treat calves with sepsis with good clinical results using a dose of 5 mg/kg twice a day.* The label dose of 1 mg/kg once a day may not achieve minimal inhibitory tissue drug concentrations for some bacteria commonly isolated from neonates. Deviation from the labeled dose requires implementation of a withholding period. Information regarding drug withholding times for extra-label use of antimicrobials is available from the Food Animal Residue Avoidance Databank (FARAD), and a database of U.S. Food and Drug Administration (FDA)–approved drugs is accessible via the World Wide Web (http://www.farad.org/index/html).

18.6.3

Circulatory Support

Maintenance or restoration of effective circulating volume is a top priority in cases of sepsis. Aggressive intravenous fluid therapy is the mainstay of cardiovascular support and should be administered at the maximal rate tolerated by the foal. Severe septic shock may require fluid rates of 40 to 80 mL/kg/hr. Volume expansion should be achieved using a balanced electrolyte solution (crystalloid) or plasma (colloid). Colloid solutions are preferred and may reduce the incidence of pulmonary and systemic edema during fluid resuscitation. Infusion of crystalloid solutions equivalent to 0.5 to 1.5 times the estimated blood volume of the patient has been used, but hemodilution is a common consequence.[122] If hemodilution is severe, or if hypotension or vasoconstriction continue or recur, additional fluid administration in the form of colloid, such as plasma, or hypertonic crystalloid fluid should be considered. Additional discussion of hypertonic saline administration may be found in Chapter 44 and in other references.[123,124]

When fluid resuscitation alone is inadequate to improve cardiovascular function and restore acceptable blood pressure, pharmacologic intervention using sympathomimetic agents is necessary. Peripheral and cardiac adrenergic receptor downregulation necessitates the use of larger doses of pressor agents than usual. In patients that are hypotensive, dopamine with its combined α- and β-adrenergic and dopaminergic activity is preferred. Higher doses are required for patients in severe septic shock. If the foal fails to respond to high doses (>10 to 15 μg/kg/min) then norepinephrine, a more potent α-adrenergic agent, can be tried. Recently, NO has been shown to play a role in sepsis-induced hypotension. IV administered new methylene blue, an NO antagonist, has been used to try and reverse severe life-threatening hypotension. If oliguria continues in spite of restoration of circulating volume, diuretics such as furosemide or mannitol are used to promote renal vasodilation and urine flow.[122]

Because most foals with sepsis are hypoglycemic, a slower continuous infusion of dextrose-containing solutions should be run simultaneously with the rehydration fluids. Avoid too rapid an infusion of dextrose to avoid hyperglycemia, which can induce an osmotic diuresis that further exacerbates the dehydration.

Treatment with antiprostaglandin drugs has been found to counteract a number of the clinical and hemodynamic changes associated with endotoxemia and septic shock, including the decrease in cardiac output and systemic hypotension. They have little effect, however, on the leukopenia, thrombocytopenia, or coagulopathies that develop in septic shock.[122] Based on the effect of these drugs in models of endotoxemia in the adult horse[125,126] and neonatal calf[127] and of septic shock in other species,[122] they would be expected to be of some benefit in treatment of the septic large animal neonate. Pharmacokinetic studies of flunixin meglumine in neonatal foals suggest that, in spite of prolonged elimination of flunixin in healthy newborn foals, the physiologic activity appears similar to that in the adult, and the adult dose of 1.1 mg/kg of body weight would be appropriate in at least some patients.[128] Lower doses of flunixin meglumine, 0.25 mg/kg IV tid may be effective in ameliorating some of the signs of endotoxemia. Other treatments include plasma administration from hyperimmunized donors to treat not only FPT but to provide opsonins and improve foal neutrophil function. Plasma also represents an ideal colloid for rapid volume expansion.

Other therapies include naloxone, an opiate antagonist, which has been used experimentally to counteract the detrimental vasodilatory effects of endorphins released during sepsis. An NO inhibitor, new methylene blue, has been used to treat refractory hypotension in septic patients.[46,47] Pentoxifylline, a methylxanthine derivative, has been used for treatment of conditions characterized by inadequate regional blood flow.[129,130] The drug increases red cell deformability, reduces blood viscosity, decreases platelet aggregation, and decreases thrombus formation. Pentoxifylline administration also results in decreased plasma fibrinogen, increased action of plasminogen activators, and antithrombin III, decreased platelet thromboxane synthesis, and increased prostaglandin 1-2 synthesis. The net effect of the drug is to increase regional blood flow and inhibit coagulation. When the drug was used in animal models of endotoxic shock, it increased overall survival rates and prevented endotoxin-induced renal failure, synthesis of TNF, and coagulopathies. Horses that received the drug showed a decrease in packed cell volume (PCV) and red blood cell (RBC) sedimentation rate and beneficial effects of RBC deformability. IV doses used experimentally in horses include a single bolus of 7.5 mg/kg of body weight followed by a continuous infusion of 1.5 mg/kg/hr.[129]

291

Polymyxin B administered at low, nontoxic doses is a new investigational treatment modality being used to neutralize systemic endotoxin. Low doses of the drug result in decreased concentrations of circulating endotoxin, improved immune function, and decreased mortality rates among shock patients. Polymyxin B binds and neutralizes endotoxin in vitro and has been shown to removed endotoxin from the circulation in vivo. Use of this drug in the horse is investigational. A suggested dose is 6000 IU/kg diluted in 300 to 500 mL of 5% dextrose and given as a slow intravenous infusion.

18.6.4 Immunologic Support

When FPT of antibodies accompanies neonatal infection, plasma is routinely used to increase immunoglobulin levels. From 1 to 4 L of plasma have been infused IV to raise IgG levels, but the optimum amount is not known. Important factors influencing the amount of plasma indicated include the total IgG content of the plasma and the specific antibody concentration against foal pathogens, as well as the degree of circulatory impairment of the neonate. The efficacy of plasma in the prevention or treatment of septicemia in foals has not been established as of this writing. See Chapter 53 for more information on treatment of FPT.

Several immunologic products are currently under investigation as potential treatments of foal septicemia; their efficacy has not yet been proven. These include serum or plasma containing high levels of antibodies to the common core structures of LPS,[126,131] and granulocyte colony-stimulating factor, which markedly increases WBC counts in foals.[132] Monoclonal antibodies to TNF and other inflammatory mediators may also be of use in the future.[133]

Bovine colostrum supplements are commercially available. Immunoglobulin content varies among products and should be considered when comparing prices. Colostrum supplements generally fail as colostrum substitutes because of the relatively low mass of immunoglobulin delivered per dose.[134] In two separate clinical trials, peak serum immunoglobulin concentrations were not significantly different in calves fed 3 or 4 L of maternal colostrum with or without colostrum supplement.[134,135] Administration of a colostrum supplement before 18 hours of age is indicated when an adequate supply of colostrum is not available. If a colostrum supplement is to be used as a colostral substitute, multiple doses are required to deliver a minimum of 100 g of immunoglobulin.

18.6.5 Supportive Therapy

Nutritional support of neonates with sepsis is critical. Gram-negative bacterial sepsis disrupts intermediary metabolism, increases metabolic rate, and sequentially hinders use of carbohydrates, lipids, and finally protein for energy. Endotoxin release precipitates a neurohormonal cascade of events mediated by TNF and increased levels of catecholamines, glucocorticoids, and glucagon. Elevated concentrations of antidiuretic hormone, aldosterone, and thyroxin and low levels of insulin accompany low perfusion states associated with septic shock. Sepsis results in glycolysis, lipolysis, and proteolysis, increased urinary excretion of potassium and nitrogen, and water and sodium retention. Suppressed insulin production and peripheral insulin resistance result in glucose intolerance and hyperglycemia. During sepsis the transport, oxidation, and clearance of free fatty acids (FFAs) is impaired owing to a deficiency of the carrier peptide carnation and decreased lipoprotein lipase activity. Lipemia develops. The final fuel source becomes protein degradation. Uremia, production of false neurotransmitters, hepatoencephalopathy, and neurologic signs occur when excessive amino acid degradation overwhelms hepatic metabolic capacity.

Provision of adequate nutrition is vital for a successful outcome in the treatment of infected neonates. Poor nutritional support leads to debilitation, a poorly functioning immune system and poor healing, persistent infection, and other complications, such as decubital ulcers. The healthy newborn foal requires 15% to 25% of body weight in milk per day. Foals that are too weak to nurse from the mare or a bottle should be tube-fed a minimum of 10% of their body weight per day in milk administered in small feeds every 2 to 3 hours. Because many sick foals have poor gut function, enteral nutrition is not a viable option initially. If a foal is not consuming at least 10% of body weight in milk within the first 36 to 48 hours, it should be started on parenteral nutrition using a formula containing dextrose, lipids, amino acids, vitamins, and trace minerals. Solutions of 5% to 10% glucose can be administered to help maintain a normal blood glucose level. These solutions provide temporary nutritional support but do not contain nearly enough calories for long-term nutritional support. It would require 35 L of a 5% dextrose solution per day to provide a 50-kg foal with adequate calories (120 kcal/kg/day). The use of a combination of oral and parenteral nutritional support has considerable merit in treating the infected neonate.

Foals with sepsis are susceptible to pulmonary dysfunction because of a variety of factors including dependent lung atelectasis, pneumonia, pulmonary edema, and surfactant dysfunction. The focus of respiratory support is to minimize ventilation and perfusion mismatching. Fluid therapy helps increase left ventricular, left atrial, and

diastolic pressures to create more uniform lung perfusion. Recumbent foals should be turned and repositioned frequently to minimize dependent lung atelectasis and pulmonary edema formation. Mild to moderate hypoxemia can be treated with humidified intranasal oxygen (2 to 10 L/min). Severe hypoxemia (P_{O_2} < 50 mm Hg), despite oxygen supplementation, and persistent hypercapnia (P_{CO_2} <65 to 70 mm Hg) require positive pressure ventilation with positive end expiratory pressure (PEEP) to prevent further lung collapse, reduce interstitial edema, and prevent respiratory muscle fatigue. Debilitated foals with sepsis that require mechanical ventilation and nasotracheal intubation are at increased risk for nosocomial infections. Nebulization using bronchodilators, wetting agents, and mucolytic agents, accompanied by coupage therapy, also helps relieve foals with respiratory distress and facilitates removal of tracheal secretions.

The nursing care of the neonate with sepsis is very important. Maintenance of body temperature; fluid, blood gas, and acid-base balance; and a clean environment is critical for a successful outcome. Every neonate undergoing intensive care, regardless of its primary problem, should be monitored closely for fever spikes, neutropenia, increasing lethargy, and localizing signs of infection that could indicate early sepsis or a different, bacterial infection resistant to the antibiotics being used.

291

292

18.7 PROGNOSIS AND COMPLICATIONS OF SEPTICEMIA AND RELATED INFECTIONS

If a large animal neonate has FPT and is septicemic with several organ systems involved, its long-term outcome must be considered guarded, even with intensive nursing care.[8] A recent study reported a short-term survival rate of 81% for neonatal intensive care unit survivors.[11] Secondary complications that often accompany multifocal bone and joint infections may exert an adverse effect on the final outcome. A retrospective study that examined the factors associated with prognosis for survival and athletic use in foals with septic arthritis showed that with treatment the prognosis for survival was favorable, whereas the prognosis for ability to race was unfavorable. Approximately 78% of treated foals survived, and a third of those foals raced. Multisystem disease, isolation of *Salmonella* species from synovial fluid, involvement of multiple joints, and synovial fluid neutrophil count <95% were associated with a poor prognosis.[136] If blood cultures are negative and localized infection (enteritis, pneumonia) is present, the outcome can be much more positive with aggressive therapy. If in utero acquired infections in the foal are treated appropriately early in the clinical course and good IgG levels are attained by the newborn, the outcome can be quite favorable (>75% survival).

19 Chapter 19 Manifestations and Management of Disease in Foals

Guy D. Lester

19.1 MATURITY

Guy D. Lester

19.1.1 GESTATIONAL PERIOD

In contrast to most other domesticated species, in mares the duration of the gestational period is highly variable. The gestational age is typically calculated from the day of insemination to the day of parturition, a value that may overestimate the true gestational period by as much as 7 days. The mean gestational length in the thoroughbred is consistently reported to be 340 to 342 days,[1–5] but the range of normal gestational ages is wide, with an estimated 95% confidence interval of 327 to 357 days.[1] The mean duration of pregnancy also appears to be relatively consistent across breeds: Friesians, 332[6] or 338[7] days; Arabians, 332 days[8]; Dutch Freiberger mares, 336 days[9]; draught breeds, 343 days[7]; Haflinger ponies, 341 days; Fjord ponies, 342 days; Shetland ponies, 337 days[7]; and ponies in England, 333[5] or 325 days.[10] Several factors appear to determine the length of gestation in mares. Colts on average have a longer gestation than fillies, with a reported difference of 1.5 to 2.5 days.[2–4,6] Colts are also heavier, have a heavier placenta, and take longer to stand.[4] The time of conception within the breeding season affects the duration of the gestational period. Mares that conceive early in the breeding season have longer pregnancies than those bred toward the end of season. This difference may be as great as 10 days.[1,2] An influence of mare, sire, and dam's sire on gestational length was recently reported in Friesian mares[6] and an effect of sire was reported in Freibergers.[9] A study of thoroughbreds concluded that dam, in addition to foal gender and month of conception, but not sire, had a significant effect on the duration of pregnancy.[2] The age or parity of the mare does not appear to have an influence,[2,3] but maternal age has been correlated with decreasing foal birthweights. Twinning is also an important cause of shortened gestational periods and in utero growth retardation.[11]

The terminology associated with birth maturity in most species is straightforward but is difficult in horses because of the variability in normal gestational length. Retrospective studies report wide variability in gestational age but unfortunately do not report physical characteristics or foal survival. Gestational ranges of 305 to 365 days, 315 to 387 days, and 286 to 370 days have been described.[2,3,12] The term *"premature"* in other domesticated animals and in human beings refers to the birth of an infant or animal after a gestational period shorter than normal. A premature human infant is now defined as one who is delivered at least 21 days before the mean pregnancy duration of 266 days. The use of a gestational age to classify equine prematurity has been described, with the most commonly used definition being a foal born before 320 days of gestation.[5] This definition was based on significantly lower birthweights and poor outcomes of foals born before 320 days.[13] It could also be argued that foals born outside the lower 95% confidence interval of the normal gestational period would best fit the classification of premature; this would be less than 325 days in thoroughbreds, using data extrapolated from Hintz and others.[3] It is clear that any precise classification of prematurity based solely on estimated gestational age would falsely classify a small number of appropriately mature animals. There are similar difficulties in classifying animals that have experienced a longer than normal gestational period. Again,

using the upper confidence interval limits from thoroughbreds, foals born after 356 days could be regarded as postterm. A distinction should be made between postterm and postmature, the latter describing a condition of increased neonatal morbidity as a consequence of failing placental function.

Dysmaturity is a term commonly used to describe foals that have experienced some degree of intrauterine growth retardation (IUGR). Such foals typically demonstrate some signs of physical immaturity, such as a low birthweight. Dysmature foals can have shortened, normal, or prolonged gestation lengths. Other terms used to classify foals with incomplete maturation include *viable* and *nonviable*[13] and *ready* and *unready for birth*.[14] In a review of terminology, Koterba suggested the terms *viable* and *nonviable* were inappropriate because outcomes of premature foals are heavily influenced by access to facilities and the value of the animal.[13] The concept of *readiness for birth* was used to categorize foal outcomes based primarily on the degree of maturation of the fetal hypothalamus-pituitary-adrenal (HPA) axis. Although this plays a critical role in determining postpartum survival, other factors, including the degree of physical maturation and the consequences of an adverse intrauterine environment, are also relevant in determining the ultimate outcome.[13] Premature maturation of the HPA axis often takes place at an inappropriate developmental stage for some body systems, causing asynchrony of organ maturation and postnatal problems.[15] Extending the concept of readiness for birth, Rossdale introduced the term *twilight foals* to describe those foals with accelerated but incomplete maturation of the HPA axis at the time of birth.[5,16]

The physical characteristics associated with prematurity include a low birthweight and small body size, a short and shiny haircoat, a prominent rounded head, periarticular laxity, and droopy ears. Foals typically have moderate flexor laxity with elevation of the toe, but some have contracture of the fetlock. Muscle development is usually poor. Most demonstrate generalized weakness and hypotonia and have difficulty in standing. Severely premature foals may have lids naturally sutured closed and little hair covering their bodies. Many have difficulty in maintaining body temperature, blood pressure (BP), and blood glucose.

Dysmature foals commonly experience some degree of IUGR. This is usually reflected by the birth of a foal that is small for its gestational age. The average relative weight of the term foal to its dam is approximately 10%. Postmature foals usually have an acceptable birthweight with a large frame but poor muscle development. This gives the foal a lanky appearance. In contrast to premature animals, fetlock contracture is common, although laxity can be present. Consistent with their prolonged gestation, postterm or postmature foals often have erupted incisors and a long haircoat. In term foals the central incisors typically erupt during the first 5 to 7 days of postnatal life.

19.1.2 CAUSES OF PREMATURE DELIVERY

The pregnant uterus is highly responsive to contractile agents such as oxytocin and prostaglandins throughout gestation. Consequently, one of the most important causes of premature birth and perinatal morbidity and mortality is the induction of labor with exogenous oxytocin or prostaglandins. The adverse consequences of premature induction of parturition were identified in a study in which parturition was induced either before 300 days' gestation or between 300 and 320 days' gestation.[17] The overall survival rate was only 5%, with the youngest surviving animal delivered after 318 days' gestation. Other surviving foals were all delivered after 320 days' gestation. The decision to prematurely terminate a pregnancy may be made deliberately in the “normal” mare, or the termination may be necessary because of significant maternal disease. The latter frequently involves delivery of a compromised and often premature foal by cesarean section. Chemical induction of parturition sometimes occurs when late pregnancy intestinal problems are misinterpreted as ineffective labor. Premature

birth can occur as a sequela to placental problems, including placental infection, edema, and/or detachment (premature placental separation). Placental insufficiency as a result of twinning is another cause of IUGR.

The consumption by pregnant mares of tall fescue pasture infected with *Neotyphodium coenophialum* leads to range of abnormal signs including prolongation of gestation, perinatal mortality, and agalactia.[18] The large skeletal frame of the postmature foal predisposes mares to dystocia. The delay in parturition may be caused by toxin-induced interference with fetal corticotropin-releasing hormone (CRH) and delay in maturation of the HPA axis. Foals born to mares grazing endophyte-infected fescue pasture have normal thyroxine and reverse T_3 but reduced triiodothyronine levels compared with control foals.[19] This is also consistent with failure of cortisol-induced maturation of thyroid function. A syndrome of congenital hypothyroidism has been reported in foals in Western Canada.[20] Signs include prolonged gestation, dysmaturity, and a range of musculoskeletal abnormalities including flexural deformities, delayed ossification, and mandibular prognathism. The specific cause has not been determined, although consumption of diets that contain nitrate or are deficient in iodine is suspected.[21]

19.1.3 MATURATION OF THE FETAL HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

The maturation of several organ systems coincides with changes in the fetal HPA axis.[15] Fetal cortisol is critical for organ maturation, but if the fetus is exposed too early in gestation or to too large a quantity IUGR may occur. The fetus is protected from cortisol during much of gestation. The type 2 isoform of the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD) converts excess biologically active cortisol into inactive cortisone in the placenta, thereby reducing the exposure of the fetus. The postnatal adrenal gland, under the influence of ACTH from the pituitary, can readily synthesize cortisol from cholesterol and pregnenolone (P5). Several important enzymes are required for this conversion, including 3β-HSD, P450scc, and P450C17. These enzymes are either inhibited or deficient during most of pregnancy, again protecting the developing fetus from excessive cortisol. Consequently during the majority of gestation the major products of steroidogenesis are progesterone and the 5α-reduced progestagens and not cortisol.[22] Foals, like other species studied, undergo enhanced adrenal activity before birth. This is reflected by high plasma cortisol and ACTH concentrations in term newborn foal plasma in the first hours after birth.[23] There is also a substantial change in the amount and localization within the adrenal gland of 3β-HSD, P450scc, and P450C17 around the time of birth.[24]

294

295

The trigger(s) for the process that results in fetal cortisol production, organ maturation, and birth are not known. Data from sheep indicate that upregulation of CRH messenger ribonucleic acid (mRNA) in the fetal hypothalamus and proopiomelanocortin in the fetal pituitary is a key initiating event.[15,25] At the same time there is upregulation of adrenocorticotropic hormone (ACTH) receptors and key steroidogenic enzymes in the fetal adrenal glands. The consequence is a progressive increase in circulating ACTH and cortisol in the fetus. The rise in fetal cortisol has a direct effect on the placenta to increase prostaglandin H synthase 2, leading to secretion of prostaglandins such as prostaglandin E_2 (PGE_2).[15,25,26] Prostaglandins further stimulate the fetal HPA axis, stimulate placental 11β-HSD-1 (which favors the production of cortisol from cortisone), and also facilitate the conversion of estrogen from pregnenolone. It is not known if these events occur in the pregnant mare, but they do appear to be consistent across most species studied.

An important difference between equids and other species is the timing of these events before parturition.[15] In pregnant ewes, maturation of the HPA axis occurs during final 20 days of a 150-day gestation. In contrast, the production of significant fetal cortisol appears to occur during the final 48 to 72 hours of pregnancy in mares.[27] Several important maturational events appear to be tightly associated with the prepartum increase in ACTH and

cortisol.[22] These include changes in red blood cell (RBC) and white blood cell (WBC) parameters, most notably a large increase in the neutrophil-to-lymphocyte ratio (N:L).[27,28] Hepatic and renal glucose-6-phosphatase, a key enzyme of gluconeogenesis, also increases sharply around the time of birth,[29] coinciding with increases in hepatic and skeletal muscle glycogen stores.

The prepartum rise in plasma cortisol likely induces deiodination of the outer ring of T_4 to produce the biologically active triiodothyronine (T_3).[30] Adequate levels of T_3 are required for a number of biologic functions including postnatal thermogenesis. Normal term foals have very high levels of thyroid hormones, including T_3, at the time of birth.[31] These levels decline over the initial weeks or months of postnatal life. A relationship between circulating T_3 levels and cortisol was reported in premature, dysmature, and mature foals,[16] and the increase in T_3 appears to be dependent on maturation of the HPA axis.[32] Both cortisol and T_3 are critical for lung maturation, particularly the normal postpartum reabsorption of lung liquid.[32]

19.1.4 ACCELERATED MATURATION OF THE FETAL HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

Several factors can induce premature maturation of the fetal HPA axis. Hypoxemia is a potent stimulator of the axis in sheep, with rises in fetal ACTH and cortisol.[33] The HPA axis can also be manipulated using exogenous glucocorticoids; betamethasone is commonly administered to women in danger of preterm birth in order to hasten HPA maturation and therefore improve the chances of postnatal survival. Poor nutrition before and after conception in sheep produces a shortened gestational period and hastened maturation of the fetal HPA axis.[25] Placental and/or fetal infection also can accelerate maturation of the HPA axis. The cytokines induced by infection increase prostaglandin synthesis and decrease metabolism. Prostaglandins exert a range of actions in addition to promoting cortisol production.

The stimuli associated with precocious HPA axis maturation in foals are not well described. The exception is infection of fetal membranes, in which foals are often delivered preterm with laboratory findings consistent with axis maturation. Spatial and nutritional deprivation resulting from a thoroughbred foal placed in a pony uterus using embryo transfer also leads to premature maturation of the fetal adrenal.[10,34]

Unfortunately, many late-term maternal diseases do not appear to have a significant effect on foal maturity. Hypoxemia associated with anesthesia and colic surgery in pregnant mares during the final 60 days of pregnancy results in a high rate of preterm delivery of compromised foals that did not survive.[35] It is likely that the insult in these cases was so severe that the interval between surgery and delivery was inadequate for maturation of the axis to occur. Another important consideration in determining outcomes would be the effect of hypoxia and/or ischemia on other fetal organ systems.

19.1.5 TREATMENT OF THE AT-RISK LATE PREGNANT MARE

Unfortunately, the administration of corticosteroids to the pregnant mare appears to have little effect on maturation of the fetal HPA axis, at least when doses considered safe are used.[5] Direct injection of $ACTH_{1-24}$ to the fetus results in increased fetal cortisol, but the effect is dependent on gestational age, with maximal responses occurring at around day 313 and with no measurable benefit when administered before day 295.[27] Direct administration of CRH, ACTH, or betamethasone to the fetus using ultrasound-guided intramuscular (IM)

injection results in increased maternal progestagen levels consistent with maturation of the fetal adrenal gland.[36,37] The procedure itself can lead to abortion in a small number of mares. Exogenous $ACTH_{1–24}$ administered to late pregnant pony mares had an impact on both gestational length and fetal maturation.[38] Depot $ACTH_{1–24}$ given to mares at 300, 301, and 302 days of gestation produced a shortened gestational length and lower birthweight but evidence of HPA axis maturation. A confounding effect in this study was the time of conception, with the most significant findings observed in mares bred later in the breeding season.

It is preferable to maintain the fetus in utero to ensure not only adequate HPA axis maturation but also effective ossification and maturation of other body systems. Consequently, the primary focus of therapy for a mare with placental infection is to eliminate the pathogenic organisms, reduce inflammation, and maintain the pregnancy. The specific management of placentitis is not the focus of this chapter, but treatment may involve broad-spectrum antibiotics, nonsteroidal antiinflammatory drugs, pentoxifylline, β_2-adrenoreceptor agonists, and altrenogest. The efficacy of altrenogest use in mares with placentitis has been questioned.[22]

The termination of postterm pregnancies is a difficult decision for practitioners, particularly with the emotional response that is common in many owners. Given the wide variation in gestational range it is almost always in the best interests of the foal to let the pregnancy continue. If facilities are available then rectal and transabdominal ultrasound assessment of the fetus and chorioallantois should be made, looking carefully for thickening or detachment of the fetal membranes. Ideally any induction of parturition should be based on appropriate changes in physical characteristics of the mare and in milk electrolytes. Mares grazing endophyte-infected tall fescue can be medicated with dopamine receptor antagonists, such as domperidone.[18]

295

296

19.1.6 LABORATORY ASSESSMENT

The laboratory data will indirectly reflect the degree of HPA axis maturation. Premature or dysmature foals that fail to survive often have minimal cortisol secretion in the face of adequate endogenous ACTH. Furthermore, the change in plasma cortisol in response to exogenous $ACTH_{1–24}$ (0.125 mg IM) is inconsistent and usually inadequate.[23] The foal with incomplete adrenal maturation will have low total white cell and neutrophil counts and an N:L that is characteristically less than 1:1.[28] It is important to determine if sepsis is present as neutropenia is also a common feature of this condition. Evidence of shifting toward immature cell types and neutrophil toxicity should indicate primary sepsis or prematurity or dysmaturity complicated by sepsis. Premature foals that fail to improve their total WBC and neutrophil counts over the initial 24 to 48 hours of treatment have an even poorer prognosis for survival. Changes in red cell indices have also been reported in nonstressed preterm foals.[28] Most notable is an elevated mean corpuscular volume in preterm foals. An elevated plasma fibrinogen concentration is considered to be a good prognostic factor in premature foals as it often reflects prepartum exposure to bacterial infection. Induced or spontaneously delivered term foals have a significantly higher plasma glucose concentration than premature foals.[39] Plasma creatinine levels are often elevated in newly born preterm or dysmature foals as a result of placental dysfunction. This increase is independent of foal renal function. Measurement of low cortisol levels coupled with increased progestagens would provide further evidence that effective maturation of the HPA axis has not occurred in the foal before birth.[40]

19.1.7 ESTABLISH A PROGNOSIS

The prognosis for survival of a prematurely delivered foal is dependent on a range of factors including the gestational age, the reasons for delivery, complications associated with delivery, available resources (facilities

and expertise), and financial limitations of the owner. Survival of very premature foals (280 to 300 days) would typically require a history of chronic in utero stress with resultant precocious maturation of the HPA axis and critical organ systems. The majority of such foals would still require a lengthy and costly period of hospitalization and experience a range of complications, some of which could be life-threatening. Foals delivered prematurely as a consequence of chemical induction of parturition without evidence of chronic in utero stress or via cesarean section typically have a high mortality rate even when delivered close to calculated due dates. Foals delivered under these circumstances before 300 days will almost certainly die, irrespective of available resources.

A complete blood count (CBC) and fibrinogen estimation are key factors in determining short-term prognosis. A normal or elevated neutrophil count, N:L, or total WBC count is a positive indicator for survival, as these values typically reflect maturation of the HPA axis. In a survey of 135 neonates admitted to the University of Florida with a gestational age of ≤320 days, short-term survival was in part predicted by total WBC count, neutrophil count, lymphocyte count, and the N:L at presentation.[41] The N:L of surviving premature foals (12.5:1) was well above that reported for both normal term foals (2.5:1) and nonsurviving premature foals. Many of the surviving animals were exposed to confirmed or suspected placental infection. Outcome was not affected by gestational age (surviving foals 311 days and nonsurvivors 307 days). These data confirm that in utero stress, with hastened maturation of the HPA axis, is a good prognostic factor for survival in foals that are delivered preterm. In many foals the greater the neutrophil count the better the outlook, at least in terms of short-term survival. A high plasma fibrinogen concentration is also considered to be a positive factor. Reevaluation of the white cell indices on day 2 for appropriate increases also supports a favorable prognosis.

A history of placental infection appears to be a positive factor when predicting survival in preterm foals. One obvious downside is that many of these foals are born with aspiration pneumonia (a result of in utero aspiration of contaminated amniotic fluid) and/or systemic sepsis. This, coupled with the fact that many foals have an impaired immune system, warrants the use of broad-spectrum antimicrobial therapy.

Consideration should also be given to the long-term outcomes of preterm foals. These animals are at risk for significant and permanent musculoskeletal problems as a result of bone and ligamentous immaturity. Foals that survive the neonatal period are smaller than their peers, and this difference will often remain noticeable when they are weanlings and yearlings. The differences may be less obvious at 2 years and older. Other common complications, such as pneumonia, will further reduce the growth rate in the first 6 months of life. There is nothing to indicate that premature fillies will experience fertility problems as adults.

19.1.8 CLINICAL PROGRESSION

The clinical progression usually reflects the degree of endocrinologic maturity, additional perinatal stresses, and the extent of physical maturity. Typically, foals born prematurely but chronically exposed to an appropriate in utero stress such as placental infection will appear weak and depressed in the immediate postpartum period. Some will require resuscitation. After a longer than normal period of postural adaptation they will usually manage to stand but will often require assistance. Suckle reflex and appetite may be reduced or absent, and many will need to be fed initially via nasogastric tube. They will frequently have trouble maintaining their body temperature and blood glucose levels. After the initial 24-hour period many of these foals demonstrate improvement both in physical strength and mentation. Their appetite for milk will often exceed that of a healthy term foal. Foals with inadequate maturation of the HPA axis will frequently require immediate resuscitation. They may mimic the clinical progression of in utero stressed premature foals until 12 to 18 hours of age. This initial period after delivery can be deceptive, with many foals showing degrees of improvement, which often promote owner optimism. The rise of hormones accompanying delivery may lead to improvement in alertness

and strength. However, after this period a range of progressive abnormalities develop. These include systemic weakness, depression, seizures, respiratory failure, and intolerance to feeding. Cardiovascular collapse may ensue, the first sign of which is a reduction in the intensity of peripheral pulses, followed by a reduction in urine flow, development of subcutaneous edema, and deteriorating neurologic function. Poor tissue perfusion leads to lactate accumulation and a mixed metabolic and respiratory acidosis. Death will certainly occur without aggressive support, and even with high-level intensive care the mortality rates are very high.

19.1.9 TREATMENT OF THE PREMATURE OR DYSMATURE FOAL

296
297

It is critical to perform a thorough physical examination, as problems of altered maturity can involve many organ systems. Successful outcomes are dependent not only on careful management of identified problems but also in predicting the problems that may arise in the hours, days, or weeks to come. Most premature and dysmature foals experience some degree of pulmonary insufficiency. Factors that predispose these foals to respiratory problems include structural and functional immaturity, a naïve and potentially immature immune system, altered pulmonary vascular reactivity, a highly compliant rib cage, and a propensity for prolonged or persistent recumbency. Final maturation of the respiratory system appears to be highly dependent on a functional HPA system. Arterial blood gas (ABG) analysis is an important tool in the assessment of respiratory function, and the lower arterial oxygen concentration in term newborn foals is further decreased in dysmature or premature foals. Extrapulmonary shunts account for more than 30% of the cardiac output, in contrast to <10% in normal full-term foals.[42] Ventilation-perfusion mismatching also occurs because of a poorly reactive pulmonary vasculature and dependent atelectasis. Deficiency of lung surfactant is not likely to play a primary role in the respiratory dysfunction in most premature or dysmature foals, as it is usually fully developed in most foals by 300 days, but it could be delayed until after 340 days in some foals.[43] The most severe form of respiratory failure is neonatal respiratory distress syndrome (RDS), a disease characterized by progressive respiratory failure, severe hypoxemia and hypercapnia, coma, and death. A diffuse severe alveolar pattern is a classic radiographic finding. Intervention would ideally involve mechanical ventilation, bovine or synthetic surfactant, and glucocorticoids; however, outcomes are extremely poor, irrespective of the level of care. Fortunately RDS is relatively uncommon; most premature foals will, however, demonstrate a less severe manifestation of lung dysfunction characterized by reduced ventilation capacity, tachypnea, hypoxemia, and varying levels of hypercapnia. These foals are very susceptible to dependent lung atelectasis from recumbency. Most foals will benefit from supplemental intranasal oxygen with initial flow rates of 5 L/min recommended. Adjustment in flow rate is dictated by positive changes in ABG analyses or improvement in ventilation rate and depth. It is important to avoid prolonged periods of lateral recumbency in order to minimize the impact of atelectasis. If the foal is unable to stand, then placement in sternal recumbency is recommended. This is made easier by use of a specially constructed V-pad.

Failure of the cardiovascular system is common in foals with partial or incomplete maturation of the HPA axis. Management is challenging in part because of inconsistent responses to standard inotrope and vasoreactive therapy. Successful treatment is reliant on early detection of reduced perfusion. This is reflected clinically by cool extremities, the presence of limb and ventral edema, and darkening of the mucous membranes with prolongation of the capillary refill time. As failure ensues, peripheral pulses will become difficult to palpate, blood pH will fall, and there will be increases in plasma lactate and anion gap. Indirect (or direct) measurement of mean BP along with determination of blood lactate will help guide therapy. An initial approach to the treatment of failing perfusion may involve intravenous plasma followed if necessary by dopamine (3 to 5 μg/kg/min) and/or dobutamine infusion (5 to 20 μg/kg/min). The volume and type of fluids given should be carefully monitored, as fluid overload and hypernatremia are common. Urine output should be appropriate for the volume of fluids administered, and anuria or oliguria should be treated aggressively. This may include low-dose

dopamine or fenoldopam infusion, furosemide boluses or infusion, or mannitol infusion. Establishment of urine flow is critical in terms of survival.

Signs of gastrointestinal (GI) tract dysfunction are rarely evident on initial assessment of premature or dysmature foals; however, most will not tolerate aggressive force-feeding. These foals commonly develop intestinal stasis with reduced fecal passage, gas accumulation, and gastric distention. The combination of prolonged asphyxia and prematurity is also a risk factor for the development of necrotizing enterocolitis (NEC). Feeding should be restricted to very small volumes (e.g., 10 to 20 mL hourly) until the foal appears to be systemically stable. Concurrent parenteral nutrition (PN) is indicated in order to prevent loss of body weight. Foals should be monitored closely for signs of GI dysfunction irrespective of feeding volume or frequency. Such monitoring includes assessing fecal passage, monitoring for changes in abdominal size (assessed using a measuring tape), testing for gastric reflux if a nasogastric tube is in place, and frequently assessing with transabdominal ultrasound.

Premature and dysmature foals are susceptible to hypothermia. Thermogenic mechanisms develop late in gestation and are related to circulating T_3 levels. As discussed previously, thyroid hormone generation is closely tied to maturation of the HPA axis. Consequently problems with thermogenesis are exacerbated in preterm foals with incomplete adrenal function. Body temperature needs careful management, as rapid warming may result in peripheral vasodilatation and possible cardiovascular collapse. Initially the foal should be covered by blankets and removed from any drafts. Intravenous and oral fluids should be warmed before use. Once the foal begins to demonstrate vigor, heat lamps and circulating warm-water blankets can be used.

Premature and dysmature foals often have inadequate gluconeogenic enzyme activity and limited glycogen stores at the time of birth. Consequently most will have difficulty maintaining a normal blood glucose concentration. This is managed acutely by infusion of 10 mL/kg of a 10% dextrose solution over several minutes, followed by a constant infusion at about 6 mg/kg/min (approximately 200 mL/hour of a 5% dextrose solution to a 30-kg foal). Blood glucose should be monitored regularly to avoid hyperglycemia. Some foals with persistent hyperglycemia benefit from insulin supplementation.

Skeletal maturity is assessed by radiographing a carpus and a tarsus for evidence of incomplete ossification (Fig. 19-1). Accelerated ossification does not appear to be a feature of foals born prematurely after exposure to chronic in utero stress. Incomplete ossification coupled with periarticular laxity predisposes the premature or dysmature foal to long-term skeletal problems. Foals with incomplete ossification and more than 30% reduction of the central and/or third tarsal bones with pinching or fragmentation of the dorsal aspects of affected bones commonly develop degenerative joint disease and have a guarded prognosis for future athletic performance. Restriction of exercise is recommended in order to minimize collapse of developing carpal or tarsal bones, but forced recumbency may predispose the foal to or exacerbate pulmonary disease. Furthermore, normal load bearing encourages ossification. Periarticular laxity predisposes the premature foal to angular limb deformities that facilitate abnormal load bearing and increase the risk of cuboidal bone crush injury of the carpus or hock. Splinting and attention to hoof care are recommended if angular limb deviation develops. In most cases flexural deformities and laxities improve over time. Dorsal splints are recommended for flexural deformities involving the fetlock, and heel extensions are helpful to foals with flexural laxity.

There are several reasons why colostral transfer of maternal immunoglobulin may not occur in premature foals. Mares may have lactated prematurely or not at all, and the foal may not be able to suck. It is crucial to ensure that the premature neonate receive ample amounts of high-quality colostrum (>20 mL/kg) in the first 6 hours after birth, although the intestinal tract may not be capable of efficient colostral uptake or may not tolerate large volumes of liquid. Consequently, plasma transfusion is often used even in foals less than 18 to 24 hours of age.

297
298

A serum immunoglobulin G (IgG) level should be measured to confirm successful transfer of immunity (>800 mg/dL).

Fig. 19-1 **A**, Lateral tarsus of a 1-day-old, 305-day gestational age colt. Note the lack of ossification of the small tarsal bones. **B**, Lateral tarsus of the same foal as in **A**, at 3 weeks of age, showing irregular ossification. Without the initial radiograph, increasing ossification could have been confused with bone lysis and osteomyelitis. The foal is reported to be sound at 6 months of age.

The use of glucocorticoid therapy in the management of prematurity is controversial. Dexamethasone has been used in human medicine because of its potency, but it is associated with adverse side effects including hypertension, hyperglycemia, and catabolism.[44] Hydrocortisone has a shorter half-life and lower biologic activity and is as effective for improving lung function in preterm human infants without the side effects of dexamethasone.

19.2 WEAKNESS AND/OR DEPRESSION

Wendy E. Vaala

Guy D. Lester

When confronted with a neonate with the primary complaint of weakness with or without accompanying depression, a number of differential diagnoses must be ruled out (see Box 20-1). The gestational and postnatal age of the neonate should be established. If weakness has been present since birth, then in utero acquired bacterial or viral infections, birth asphyxia and trauma, chronic placental problems, and congenital anomalies should be placed higher on the list of differential diagnoses. Lethargy and loss of suckle are often the first signs of neonatal illness. A full udder on the dam accompanies poor nursing behavior in the neonate. If the neonate is depressed and has injected mucous membranes and hyperemic coronary bands, then sepsis is the primary differential diagnosis and the most life-threatening. If the neonate is relatively bright but is becoming a "dishrag," consider peripartum hypoxia and early signs of hypoxic-ischemic encephalopathy. If the newborn shows signs of physical immaturity such as tendon laxity and silky hair coat, then weakness may be a result of progressive fatigue, hypothermia, hypoxia, and/or hypoglycemia. Unfortunately, many weak foals begin to fade as a result of multiple problems. Glycogen branching enzyme deficiency in certain quarter horse and Paint lineages is associated with a range of abnormal signs that could include persistent recumbency.[45]

If weakness is present without accompanying depression, then several other differential diagnoses should be considered. Neuromuscular diseases include botulism, white muscle disease, and congenital myopathies. Botulism is an infection acquired via the GI tract. Consequently, signs appear in neonates that are usually 10 days of age or older. Although most cases of nutritional myodegeneration (NMD) occur during the first year of life among rapidly growing large animal neonates, an in utero form of NMD may occur, resulting in clinical signs in affected foals soon after birth. If weakness is detected in one or more limbs immediately after birth, peripheral nerve and muscle damage associated with birth trauma should be ruled out. Foals with rupture of the gastrocnemius muscle will be unable to rise or stand unsupported.[46]

It should be determined whether any drugs or anesthetics were administered to the dam before or at the time of delivery, as many agents cross the placenta and can exert depressive and other adverse effects on the fetus. For example, one study reported that phenylbutazone administered to normal pregnant mares crossed the placenta and resulted in substantial concentrations of phenylbutazone and its active metabolite oxyphenbutazone. Although clinical signs of phenylbutazone toxicity were not noted in the foals postnatally,[47] adverse effects are possible, particularly if other problems are present. Drug-induced neonatal depression is particularly important after cesarean deliveries. Maternally administered anesthetics and analgesics can suppress respiration and heart rate in the newborn. In horses, both xylazine and detomidine cause maternal and fetal bradycardia and reduced cardiac output.[48,49] These effects cause a reduction in placental perfusion and fetal oxygenation. If the newborn shows depression associated with maternal administration of these drugs, yohimbine can be given as an antagonist. Weakly basic drugs, when given to the mare, tend to concentrate in the fetus. Diazepam is an example of such a drug that crosses the placenta rapidly and accumulates in the fetal circulation, resulting in lethargy, hypotonia, and hypothermia in the neonate after delivery. Flumazenil has been used to reverse the sedative effects of benzodiazepines. Maternal systemic illnesses of various types may also result in a weak newborn.

298
299

Many neonatal disorders are associated with severe electrolyte and metabolic derangements. Weakness is a common clinical manifestation of hypoglycemia, metabolic acidosis, hyponatremia, hypernatremia, and hyperkalemia. Such abnormalities may occur before or at the time of birth, and laboratory assessment of the weak newborn is essential for accurate diagnosis. Young foals with hypocalcemia can have stiff gait, muscular tremor, tachycardia, sweating, muscular tremor, and recumbency.[50] Profound weakness associated with metabolic acidosis is commonly observed in foals with diarrhea. Correction of the acidosis by intravenous administration of bicarbonate usually produces rapid improvement.

A number of congenital bacterial, fungal, and viral infections that cause abortions and stillbirths may also result in the birth of a live, weak neonate. Clinical manifestations of fetal infections depend on the age of the fetus and virulence and trophism of the infecting agent (see individual diseases).

Generally, weakness secondary to uroperitoneum, renal, and liver failure, postnatally acquired infections, and neonatal isoerythrolysis (NI) is not expected to appear during the first 24 hours of age. Rather, foals with NI are usually presented between 24 and 72 hours of age, foals with uroperitoneum at 2 to 5 days of age or older, and neonates with postnatally acquired infections most commonly at 2 to 5 days of age or older.

NMD associated with selenium and/or vitamin E deficiency may produce localized (dysphagia) or generalized paresis.

Paraplegia and tetraplegia are commonly associated with spinal cord compression. Compression of the spinal cord in neonates most commonly results from vertebral body malformations, osteomyelitis, or fractures. Most malformations involve the occipital condyles of the skull and the first two cervical vertebrae (OAAM). Generally, vertebral body malformations occur sporadically; genetic, nutritional, and environmental factors have been implicated. Osteomyelitis and vertebral body abscess may be a sequela to bacteremia after neonatal sepsis or pneumonia. *Rhodococcus equi* vertebral osteomyelitis with or without associated pulmonary infection has been reported in foals.[51] Leukocytosis and hyperfibrinogenemia are commonly observed in neonates with vertebral body abscesses. In most instances vertebral abscesses do not infiltrate the pachymeninges so the cerebrospinal fluid (CSF) either is normal or has a mild elevation of protein and/or a mild pleocytosis.

A complete neurologic examination is an important component of the workup of the weak neonate. In particular, it should be noted if the weakness is accompanied by signs of depression and diffuse cerebral disease. Limb reflexes should be tested to establish whether components of the spinal reflex pathways are involved in the disease process (sensory nerve, lower motor neuron, neuromuscular junction, muscle). For example, foals with severe spinal cord hemorrhage may have relatively normal mentation, but spinal reflexes may be greatly diminished and profound weakness may be present. Animals with other types of spinal cord disease (e.g., trauma, vertebral malformations) may also show weakness and ataxia yet appear clinically to have normal cerebral function. Virtually any severe systemic disease such as generalized infection can cause both profound depression and weakness in a neonate without the presence of actual brain pathology. Primary neurologic disease in neonates is rare; commonly, neurologic dysfunction is associated with multisystemic disease. A thorough comprehensive physical examination and workup are required to define a problem list and formulate an appropriate management plan. A CBC, blood cultures, and assessment of immunoglobulin status provide an indication of the likelihood of sepsis. Hypoxia and metabolic acidosis are ruled out by assessing ABG status, and electrolyte disturbances and hypoglycemia are evaluated by measuring serum electrolytes and blood glucose concentration. Collection of CSF to assess the central nervous system (CNS) is usually performed when disease in other organ systems that may account for the altered mental state has been ruled out and no improvement in the patient's condition is observed after correction of electrolyte, blood gas, and metabolic derangements.

19.3 SEIZURES

19.3.1 IDENTIFICATION OF NEONATAL SEIZURE ACTIVITY

Seizures may be generalized or partial, depending on the part of the cerebral cortex affected by abnormal electrical activity. Involuntary muscle activity, opisthotonos, paddling, and extensor rigidity are signs associated with a generalized convulsion. In the neonate, more subtle neurologic signs may also be associated with seizure

activity. In the human infant, particularly the premature infant, the neuromuscular system is not fully developed at birth and is therefore unable to fully express the abnormal electrical activity in cerebral neurons. Abnormal breathing patterns, lip smacking, chomping, rapid eye movements, small limb movements, and tremor may be the only signs indicating seizure activity in the human infant. Similar signs in the abnormal neonatal foal have also been attributed to seizure activity.[52]

In the large animal neonate, several conditions should be distinguished from seizure activity. Bizarre movements associated with rapid eye movement (REM) sleep, particularly prominent in the premature foal, are frequently confused with seizure activity by the inexperienced observer. Signs can be very similar and include rapid eye movements, rhythmic paddling of the limbs, and chomping. The two conditions can be distinguished by attempting to arouse the animal; if activity is associated with REM sleep, the animal should be easily aroused to full consciousness. A foal that is simply resisting restraint in lateral recumbency may also appear to be having a seizure, and violent paddling of the limbs and occasionally opisthotonos are noted. If confusion exists as to the cause of the activity, the animal is encouraged to stand, and its behavior is then evaluated. Finally, in the foal the cataplexy-narcolepsy syndrome may be confused with convulsions. This “fainting foal syndrome” was first described in 1924 in three Suffolk foals that showed signs within a few hours after birth,[53] and a familial occurrence was recently reported in miniature horse foals.[54] Any exciting stimulus, including petting and restraint, can trigger the attacks, in which affected foals suddenly appear to be asleep, with flaccid limbs yet open eyes.

299
300

Once seizure activity is identified, the cause of the seizures should be identified, if possible. A complete history is obtained, including a detailed description of the delivery process, and complete physical and neurologic examinations are performed. Any signs of trauma, infection, or congenital malformations should be noted. Evaluation of hematologic data and IgG status, combined with historical and physical examination parameters, results in an assessment of the likelihood of sepsis. Blood glucose and serum electrolyte concentrations should be determined promptly. A chemistry panel, blood gas analysis, bacterial cultures of blood and other body fluids, and possibly CSF analysis and skull radiographs, complete the database in most cases.

Before attempting to collect CSF (see Chapter 35), the benefit of the information likely to be obtained must be weighed against the small risk to the patient and the inconvenience of having to analyze the sample within 30 minutes of collection. In the large animal neonate, as in the adult, either the atlantooccipital or lumbosacral site may be used. Depending on the state of consciousness of the neonate, local anesthesia with manual restraint or light sedation, or general anesthesia may be required to obtain the fluid. For collection of fluid from the atlantooccipital site, a 20-gauge, 1½-inch needle with a clear hub may be used. A change in resistance is felt when the needle penetrates the dural membranes, and CSF appears in the plastic hub as soon as the subarachnoid space is entered. Approximately 5 to 10 mL of fluid may be removed safely from foals.[52]

Urinary reagent strips can be used to rapidly obtain general information on the fluid. If blood is detected, the sample should be spun down after the cytologic examination. RBCs contaminating the sample will settle, and the supernatant should be colorless. If hemorrhage occurred before the procedure, the sample remains xanthochromic (yellow). Glucose should be present in “trace” or “+” amounts in the normal sample. Negative values in the adult suggest severe meningitis but in the neonate may also be caused by profound hypoglycemia. The total protein level is increased in neonatal foal CSF compared with the level in the CSF of the adult horse, averaging 1.38± 0.5g/L (138±50 mg/dL) during the first 40 hours after delivery,[55] and slight xanthochromia is often present. Immaturity of the blood-brain barrier is postulated as one reason for the difference in CSF protein between adult and neonatal animals.

Vascular accidents in the neonate are tentatively diagnosed on the basis of a xanthochromic sample, elevated total protein levels, increased numbers of erythrocytes, and microscopic identification of erythrophagocytosis (best). CSF analysis is most useful in determining the presence of septic meningitis. Elevation of the total protein level (>150 mg/dL) and neutrophil count in addition to a positive Gram stain and bacterial culture results in a straightforward diagnosis of bacterial meningitis, and the prognosis is considered poor for the animal.[56] However, infection in the CNS can be difficult to detect until the process becomes generalized, and the lack of positive cultures and Gram stain does not rule out CNS infection. An elevated albumin quotient suggests increased blood-brain permeability and can be seen in both hypoxic-ischemic brain injury and meningitis, but an elevated IgG index indicates increased intrathecal IgG production and is more compatible with a diagnosis of meningitis.[57]

Ultrasonography and computed tomography (CT) are important procedures for evaluating anatomic causes of seizures (hemorrhage, infarct, malformations) in the human infant. Because the fontanelles are usually closed in the large animal neonate, ultrasound imaging is of limited or no use. Premortem diagnosis of agenesis of the corpus callosum and associated malformations was made using CT scanning in a foal that had an abnormally shaped head and seizures refractory to anticonvulsant therapy.[57] Identification of the specific abnormalities early in the clinical course allowed the owners to make a more informed decision regarding the treatment of the foal, and the clinicians to acquire valuable information regarding the prognosis associated with a specific malformation in the horse.

19.3.2 TREATMENT OF SEIZURES

Generalized seizures should be controlled immediately. Diazepam is often the initial drug chosen for seizure control because of its rapid effect. A dose of 5 to 20 mg for a 45-kg neonate is slowly administered, and its effect monitored. In some individuals one dose controls the seizure, and repeat seizures are not observed, whereas in others, multiple doses at frequent intervals may be necessary. In these animals other longer-acting anticonvulsants are often required.

Phenobarbital acts by raising the seizure threshold, and its peak effect is seen at approximately 30 minutes. An initial dose of 10 to 20 mg/kg diluted in saline and given intravenously (IV) over 15 minutes has been used successfully to control seizures in clinical patients. This initial dose is followed by a maintenance dosage of 10 mg/kg IV every 12 hours. Oral tablets may also be used. The major side effect of phenobarbital in foals has been mild sedation and ataxia. Interactions between phenobarbital and other drugs usually involve induction of the hepatic microsomal enzyme system. Weaning from anticonvulsant therapy should be gradual to avoid recurrence of seizure activity.

Phenytoin has also been used for seizure control in the newborn foal. The initial dose is 5 to 10 mg/kg IV followed by 1 to 5 mg/kg every 2 to 4 hours. This dosage resulted in effective seizure control in several foals unresponsive to both diazepam and phenobarbital, but it also appeared to cause marked depression in some patients. Little is known about the pharmacokinetics of the drug in the large animal neonate.

Pentobarbital anesthesia has also been used to control seizures, but its use has been associated with marked respiratory depression, hypotension, hypothermia, and prolonged anesthesia. Xylazine is also a potent sedative in the foal, but its side effects have also included markedly depressed cardiovascular and respiratory function and prolonged recovery in abnormal foals. Neither pentobarbital nor xylazine is recommended for seizure control in the foal unless no other agents are available.

19.3.3 CONDITIONS ASSOCIATED WITH SEIZURES

CNS dysfunction in asphyxiated large animal neonates is discussed in Chapter 16. Disorders of sodium can also cause seizures in young foals; these are discussed in detail in Chapters 22 and 44.

19.3.3.1 Meningitis

Although bacterial meningitis may occur as a primary entity, it more commonly is a result of generalized sepsis in neonates with failure of passive transfer (FPT). Agents that cause meningitis are the same as those that cause septicemia, most commonly bacteria such as *Escherichia coli*, *Enterobacter* species, *Salmonella* species, and *Streptococcus* species. Because clinical signs of meningitis are easily confused with hypoxic ischemic encephalopathy (HIE) and septicemia without localization in the CNS, diagnosis depends on CSF analysis (see Chapter 35). Treatment recommendations for treating bacterial CNS infections may be found in Chapter 35. Although there is one report on the successful treatment of two neonatal foals with suspected meningitis using third-generation cephalosporins,[58] in many cases, once the diagnosis is made the infectious process is often well advanced both in the brain and in other tissues, resulting in a poor outcome.

19.4 RESPIRATORY DISTRESS

Wendy E. Vaala

Guy D. Lester

The transition from the fluid-filled lung of the fetus to an organ that is responsible for efficient gas exchange is both rapid and complicated. The process can be complicated by a number of factors, including prematurity or dysmaturity, aspiration of meconium or milk, and bacterial, viral, or fungal infection. A highly compliant chest wall, an inefficient immune system, and failure to derive adequate antibody from colostrum (partial or total FPT) are additive factors that predispose the neonate to respiratory problems.

The detection of respiratory disease in the newborn foal can be difficult. Thoracic auscultation can be highly misleading. Minute ventilation (frequency × tidal volume) is increased in the healthy neonate, resulting in easily heard bronchovesicular sounds. There is no need to accentuate breath sounds with rebreathing techniques. During the first few hours after birth, fluid can normally be auscultated throughout both lung fields and within the trachea. End-inspiratory crackles are commonly heard over the dependent lung during and shortly after rising from lateral recumbency. This is presumably because of simple atelectasis. Foals with respiratory disease will frequently have abnormal lung sounds, such as crackles and wheezes, but neonates with even severe pulmonary disease will occasionally have little detectable abnormality during auscultation. Clinical signs that are often associated with pulmonary tract disease in older foals and adult horses are frequently lacking in the sick neonatal foal. Fetal foals develop and mature in a relatively hypoxic environment within the uterus and therefore are more likely to tolerate postnatal hypoxemia than older foals or adults. Cough is also uncommon, likely owing to a postnatal delay in maturation of irritant receptors within airway and delayed onset of the laryngopharyngeal cough reflex. This is clinically relevant in that aspiration of milk into the lower airway associated with force-feeding can go undetected for several days. Of additional importance is that the respiratory rate and rhythm frequently do not accurately reflect arterial concentrations of oxygen or carbon dioxide. This is particularly relevant in foals that are showing signs suggestive of asphyxial injury, where rising arterial CO_2 concentrations occur in response to hypoventilation

and fail to cause an increase in minute ventilation. In these foals the primary drive for ventilation is arterial O_2 rather than CO_2.

In the absence of ABG data or radiographic information, the clinician must rely on vague signs, such as restlessness and agitation, increased respiratory rate, or respiratory distress. Historical information may also aid in diagnosis. This should include an estimation of gestational age, recognition of any maternal problems (e.g., fever, dystocia, placentitis, or prepartum vaginal discharge), the presence or absence of meconium staining of amniotic fluid, and an assessment of colostral quality and quantity. Failure to make an early identification of pulmonary disease often results in unfavorable outcome, with chronic pneumonia resulting. Malformations, inflammation, or other abnormalities of the upper respiratory tract can cause clinical signs of respiratory distress, stridor, and dysphagia and result in lower respiratory tract problems as well. Several nonrespiratory conditions also cause clinical signs that mimic respiratory disease.

The ideal diagnostic tools for investigation of neonatal respiratory disease include ABG analysis and thoracic radiography. ABG analysis is the most sensitive clinical tool used to assess lung function. The sample is usually collected from the dorsal metatarsal artery, easily palpated in most foals on the lateral aspect of the third metatarsal bone. Alternative sites include the brachial artery, located at the level of the medial collateral ligament of the elbow joint, and the carotid artery, but hematoma formation is a common sequel to aspiration from the latter site. The sample will remain useful for up to 90 minutes in a capped plastic syringe at room temperature.

Interpretation of the ABG sample involves consideration of the amount of struggling and position of the foal during sample collection. Normal ABG values for neonates of different postnatal and gestational ages are presented in Table 19-1. Lateral recumbency can reduce the Pa_{O_2} by as much as 30 mm Hg. The sample needs to be handled appropriately, paying strict attention to avoidance of air contamination, which will artificially increase the Pa_{O_2} and decrease Pa_{CO_2}. The inspired oxygen concentration must also be considered when analyzing ABG values. With supplemental oxygen, Pa_{O_2} is increased variably, depending on the inspired oxygen concentration (Fi_{O_2}), the amount of pathology present (particularly the extent of right-to-left shunting), the respiratory rate and tidal volume of the foal, and whether the oxygen is delivered by nasal insufflation. A flow rate of 10 L/min, delivered by nasal insufflation, increased the Pa_{O_2} to 298 ± 69 mm Hg in the normal, term newborn foal[59]; this flow rate was thought to approximate an Fi_{O_2} of 1.[60] In the induced premature foal the Pa_{O_2} increased only to 111 ± 35 mm Hg.[59] If the respiratory rate of a foal is rapid and shallow, the supplemental oxygen will be "diluted" by room air because of the large quantity of room air entering the upper respiratory tract, and the concentration of alveolar oxygen will probably be much less than 100%. The two most common respiratory-derived ABG derangements include hypoxemia with normocapnia or hypocapnia and hypoxemia with hypercapnia. It is important to distinguish acute from chronic hypercapnia. Acute hypercapnia is associated with a more substantial drop in blood pH and may lead to circulatory collapse and coma, particularly if accompanied by acute hypoxemia. Chronic exposure to elevated CO_2 permits adaptation and more subtle clinical effects. The change in pH is less dramatic, primarily because of enhanced bicarbonate reabsorption in the proximal tubules of the kidney. This effect begins within 6 to 12 hours of exposure to increased concentrations of CO_2 and is maximal by 3 to 4 days. Hypercapnia can be exacerbated by fever or the administration of carbohydrates or bicarbonate. The latter is often clinically relevant and highlights the danger of giving large amounts of sodium bicarbonate to foals with pulmonary disease.

Interpretation of blood gas values of venous blood (see Table 19-1) can be very deceptive and should be restricted to evaluation of metabolic conditions (e.g., metabolic acidosis) and not pulmonary gas exchange. To avoid problems associated with regional blood sampling, peripheral venous blood should be taken from a free-flowing jugular vein, because the metabolic status of the head is usually stable. To obtain a sample representative of the whole body, mixed venous blood is drawn from the right atrium. Determination of mixed venous blood oxygen

saturation is a good test for assessing the overall adequacy of oxygen delivery to tissues because it reflects the balance between oxygen delivery and oxygen use.

Table 19-1 Normal Blood Gas Values for Foals*

	Arterial					Venous			
Age-Group	O_2 (mm Hg)	CO_2 (mm Hg)	pH	Base Excess	HC^-_3 (mEq/L)	O_2 (mm Hg)	CO_2 (mm Hg)	pH	HC^-_3 (mEq/L)

Several factors need to be considered when evaluating foal thoracic films. Thoracic radiographs are routinely taken only in the standing or recumbent lateral position in foals, with dorsoventral positioning reserved for the anesthetized or very depressed foal. Thus interpretation can be limited because of positioning limitations. If the neonate has been in lateral recumbency for extended periods of time, atelectasis may result in diffuse or localized interstitial infiltrates that usually resolve once lung reexpansion occurs. It can be very difficult to accurately distinguish bacterial pneumonia from atelectasis and pulmonary edema on the basis of radiographic appearance alone. In these cases additional diagnostic aids (cultures, hematology, necropsy) should be used in conjunction with radiology to reach an accurate diagnosis. A false overinterpretation of disease is common because of motion artifact, caused by a combination of long exposure times, poor patient compliance, and high spontaneous ventilation rates. When the radiographic appearance of the lung fields is evaluated, the type of infiltrate (interstitial,

nodular, alveolar, mixed), severity, and location (diffuse, perihilar, cranioventral, craniodorsal, caudodorsal, caudoventral) should be noted. Other soft-tissue structures (including the heart, vessels, and diaphragm) and bones (ribs, vertebrae, long bones) should also be evaluated.

Serial thoracic radiographs are useful in monitoring the progress of a respiratory condition. Radiographic changes may either follow or precede changes in clinical condition, and major changes can occur surprisingly rapidly (Fig. 19-2). Clinical signs of pneumonia frequently resolve much earlier than chest radiographs and hemograms return to normal. Unfortunately, both ABG analysis and radiography are difficult to perform in field situations.

Ultrasonographic evaluation of the foal's thorax can yield useful information in a variety of disease processes, including pleural effusion, such as hemothorax or pleuritis, bronchopneumonia, or abscessation. It is also the preferred method for diagnosing rib fracture or dislocation and congenital heart disease and thus is often a useful technique to differentiate cardiac and pulmonary causes of hypoxemia.[61]

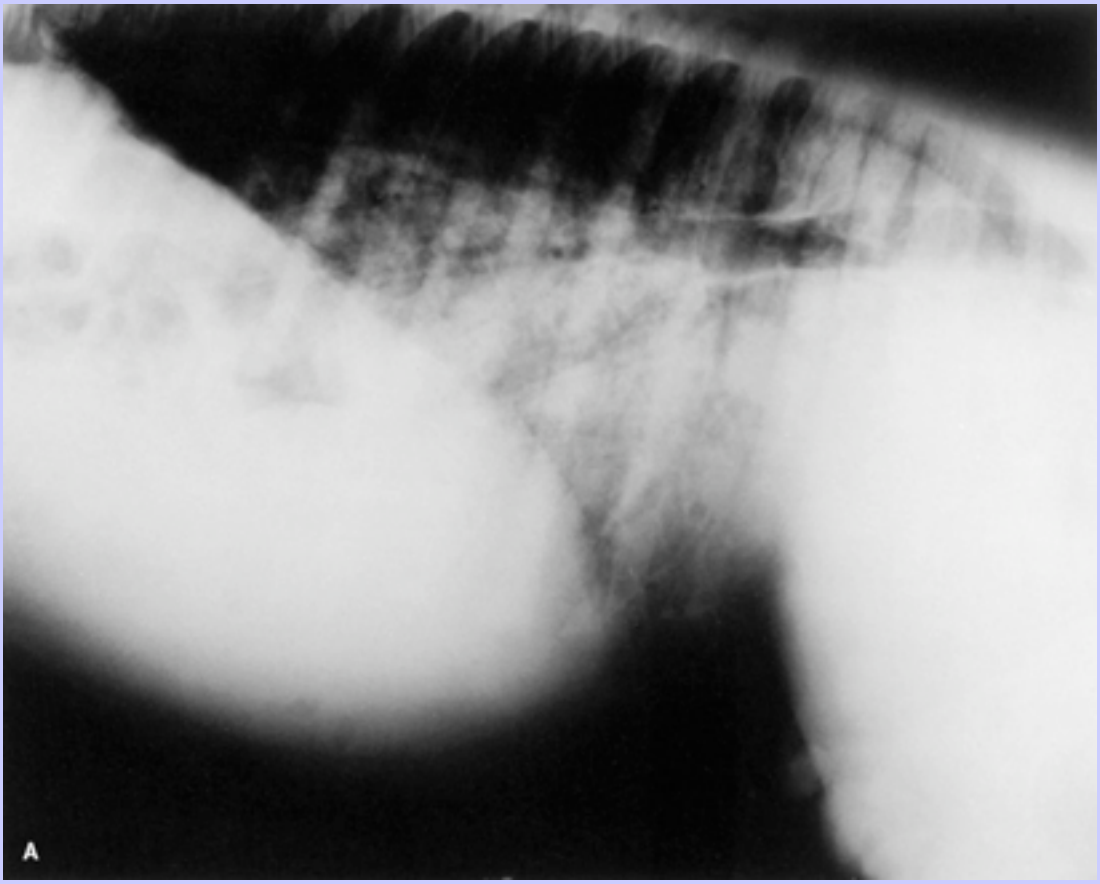
19.4.1 SPECIFIC RESPIRATORY CONDITIONS

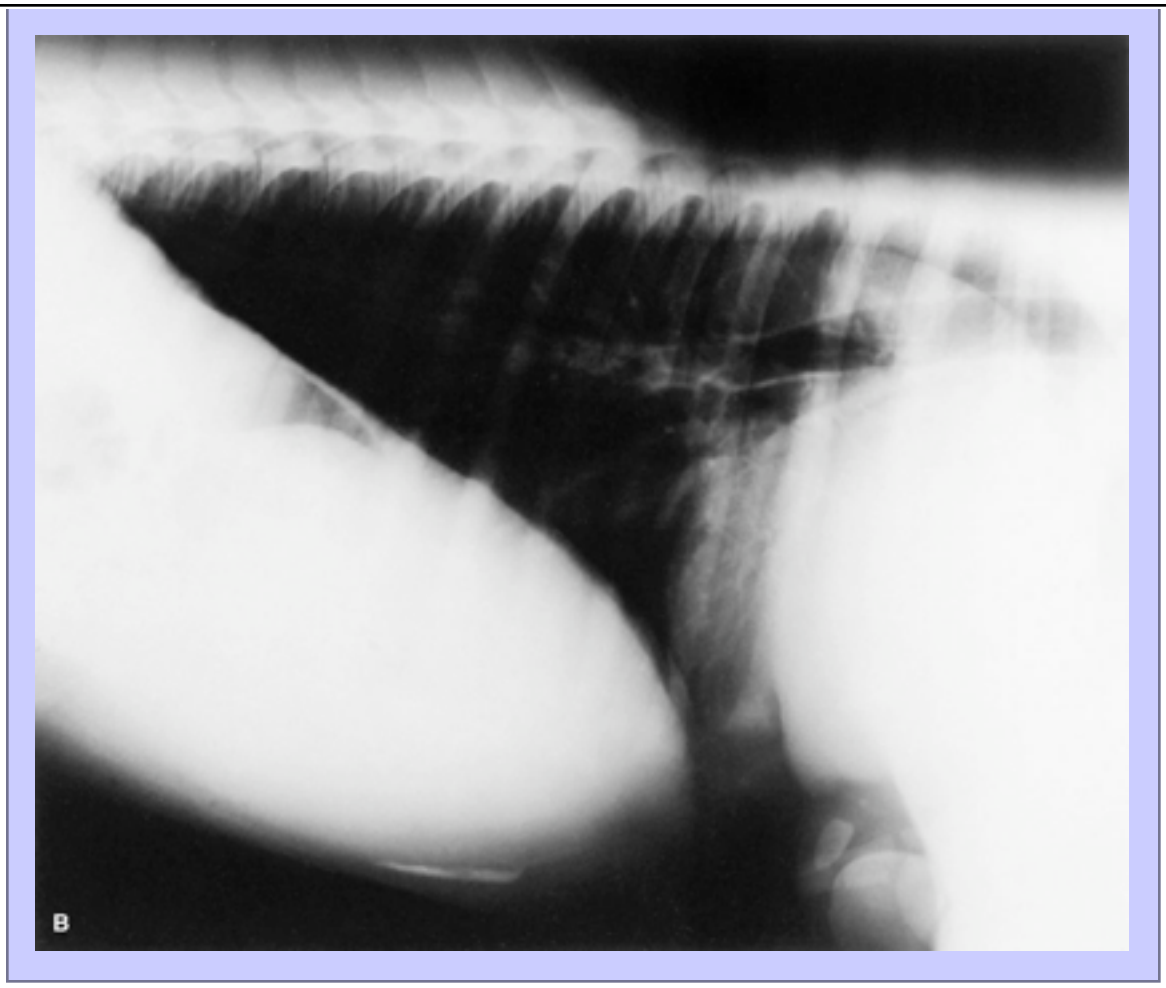
19.4.1.1 Upper Respiratory Tract Disorders

Upper respiratory tract disorders are relatively uncommon in neonates. Conditions affecting pharyngeal and laryngeal function are important, as they predispose to aspiration pneumonia. Dyspneic neonates also have difficulty nursing and are subsequently likely to become malnourished. Congenital defects of the upper respiratory tract include collapsed trachea, stenotic nares, choanal atresia, epiglottal cyst, and guttural pouch tympany (foal). There have also been recent reports of dorsal displacement of the soft palate (DDSP) as a cause of acute dyspnea, stridor, and dysphagia in neonatal foals.[62,63] Endoscopic examination of the upper airways of these foals revealed that the dorsally displaced soft palate was edematous, flaccid, and redundant. To varying degrees, flaccidity and swelling of other pharyngeal and laryngeal structures (e.g., arytenoid cartilages, epiglottis, or palatopharyngeal arch) were also noted.[63] Both medical[63] and surgical[62] treatment of the condition have been suggested. In one study, medical management with antiinflammatory drugs, enteral feeding via nasogastric tube, and broad-spectrum antibiotics (for the coexisting aspiration pneumonia) resulted in dramatic and permanent resolution of the problems within 2 to 4 days. The cause of these abnormalities remains unknown at this time but may involve primary pharyngeal and palatal muscular laxity.[63]

Impaired pharyngeal and laryngeal function may result from physical deformation or neuromuscular disorders. Pharyngeal and laryngeal injuries are often associated with improper application or use of damaged feeding tubes and oral medication equipment. Compression of the larynx by a retropharyngeal abscess or mass tends to cause inspiratory dyspnea; aspiration pneumonia is a common sequela. Partial occlusion of the upper airway induces turbulent airflow and subsequently mucosal edema. Placement of a tracheostomy tube provides an alternate, sometimes lifesaving, airway and rests the inflamed mucosa.

Fig. 19-2 **A**, Standing lateral chest radiograph of a 7-day-old thoroughbred filly with severe angular limb deformities that experienced an acute onset of severe respiratory distress and cyanosis after a walk outside the stall. Intubation and 100% oxygen administration raised the Pa_{O_2} to only 48 mm Hg. Severe pulmonary interstitial disease is present in the caudoventral lung fields, and the tentative diagnosis was bacterial pneumonia. No modifications were made in the treatment regimen (the same antibiotics being given for a wound were continued), and over the following 24 hours the filly clinically improved. **B**, Repeat radiographs taken 3 days after the first ones revealed marked resolution of the infiltrates. The diagnosis remains open, but pulmonary edema was suspected.





303

304

NMD, hyperkalemic periodic paralysis, and botulism may induce laryngeal paresis. Dysphagia and subsequent aspiration pneumonia are common sequelae of pharyngeal and laryngeal dysfunction associated with NMD and botulism. Exercise- and excitement-induced respiratory stridor has been described in foals with hyperkalemic periodic paralysis.[64]

Collapsed trachea is a rare congenital or acquired condition. Clinical signs include an intermittent honking cough, stridor, and dyspnea with mild exercise. There is no stenosis of the trachea; rather, a dynamic dorsoventral collapse during inspiration. The caudal cervical and cranial thoracic sections of the trachea in the area of the thoracic inlet are most frequently affected. Acquired tracheal collapse is commonly associated with fractured ribs and compression of the trachea at the thoracic inlet by the subsequent bony callus.

Diagnosis of most upper airway disorders can usually be made with a combination of radiography and endoscopy. A 7-mm outside diameter (OD) endoscope is usually small enough to pass through the ventral meatus of horse and pony foals that weight over 30 lb. An integral part of the diagnostic approach to the neonate with suspected upper airway obstruction is assessment of the lungs for aspiration pneumonia. If the primary upper respiratory problem is not corrected and normal nursing is allowed, the pneumonic process will likely persist and become chronic.

19.4.1.2

Respiratory Infection

Bacterial infection of the lower respiratory tract most commonly occurs during or shortly after birth but can also take place before parturition through aspiration of contaminated amniotic fluid. This may take place in mares with bacterial placentitis. In the newborn foal, pneumonia can result from direct aspiration or inhalation of bacteria or from the hematogenous spread of organisms in foals that are bacteremic. The most common bacterial organisms that have been associated with pulmonary disease in foals are identical to those that cause systemic sepsis. The most common isolates include *E. coli*, *Klebsiella pneumoniae*, *Pasturella* species, *Actinobacillus* species, and *Streptococci* species. Less common isolates include, but are not limited to, *Salmonella* species, *Enterobacter* species, *Pseudomonas* species, *Serratia marcescens*, *Staphylococcus* species, and *Yersinia pseudotuberculosis*.

The diagnosis of pneumonia involves identification of the causative organism. Isolation of bacteria can be attempted from blood culture or from culture of amniotic fluid or placental tissue if in utero infection is suspected. Lower airway culture can be difficult, as a tracheal aspiration can be dangerous in a compromised neonate. An alternative method involves passage of a guarded swab through a nasotracheal tube into the lower airway. The tip of the nasotracheal tube can also be cultured if it has been present in the airway for a prolonged period. A CBC and measurement of an acute phase protein, such as fibrinogen, may support a diagnosis of infection but will not be helpful in localization of infection to the respiratory tract. The treatment of bacterial lung disease involves a combination of respiratory support techniques and antibiotic therapy. The neonatal foal readily develops dependent atelectasis in lateral recumbency. Consequently, positioning in sternal rather than lateral recumbency results in improved ventilatory capacity and higher arterial oxygen tension. Broad-spectrum antibiotic therapy should be commenced as soon as lung disease is suspected. A good choice is a β-lactam antibiotic, such as penicillin or ampicillin, combined with an aminoglycoside. The emergence of *E. coli* resistance to gentamicin in certain regions may limit its future use. The third-generation cephalosporins, such as ceftiofur, ceftazidime, ceftriaxone, and cefotaxime, have distinct advantages over aminoglycosides in the treatment of bacterial pneumonia. They have superior penetration into the lung, and effective tissue concentrations are easily achieved by intravenous or intramuscular routes. Because premature discontinuation of antibiotic therapy has resulted in relapse in a number of cases, repeat radiographs and hematology (complete blood cell count and plasma fibrinogen) are highly recommended before discontinuation of antibiotic therapy. A minimum course of therapy of 3 to 4 weeks' duration is not unusual in cases of severe pneumonia. Premature foals with pneumonia should be monitored particularly closely for the development of bacterial pneumonia resistant to the antibiotics being used.

Several viruses have been documented as causes of pneumonia in the neonatal foal. These include equine herpesvirus type 1 (EHV-1) and type 4 (EHV-4), equine influenza, equine viral arteritis virus, and adenovirus. Of these, EHV-1 is the most common. Herpesviral pneumonia is frequently fatal, even in the face of aggressive supportive therapies such as mechanical ventilation. The antiviral drug acyclovir has been used. The difficulty is establishing a diagnosis early in the course of treatment. Several factors appear common to EHV-1–infected foals, but none should be considered pathognomonic. These include leukopenia with neutropenia and lymphopenia, and depletion of the myeloid cell lines on cytologic examination of bone marrow aspirates. The presence of dilated retinal vessels and a red discoloration to the optic disc on fundic examination has also been suggested as a common antemortem finding. Infection with adenovirus can be a problem in any immunocompromised foal, especially Arabian foals with severe combined immunodeficiency (SCID) syndrome.

In utero infection with *Histoplasma capsulatum* can result in placentitis, abortion, or birth of an infected foal with multiple organ disease, including granulomatous pneumonia. An antemortem diagnosis can be difficult to establish but is aided by tracheal aspirate and bronchoalveolar lavage when characteristic yeastlike organisms (3 to 5 µm in diameter) are seen within macrophages. Neonatal and maternal serum should be positive for anti-*Histoplasma* antibodies using an agar gel immunodiffusion test. The disease has been successfully treated in adults using amphotericin B, but reports of neonatal survival are lacking. Infection with *Candida* species (especially *Candida albicans*) is an infrequent complication in foals with chronic bacterial infection. Lengthy antimicrobial use is an apparent risk factor for infection, and many cases begin with oral candidiasis. The diagnosis is based on a history that often includes persistent low-grade fever, worsening respiratory disease or the development of synovitis, and isolation of the organism through blood culture. Successful treatment of neonatal candidiasis has been achieved with ketoconazole, amphotericin B, or fluconazole.

19.4.1.3

Meconium Aspiration Syndrome

In utero asphyxia or umbilical cord occlusion can result in fetal passage of meconium into amniotic fluid. Hypoxia induces a redistribution of blood flow away from less vital organs, including the gastrointestinal tract, resulting in mesenteric vasoconstriction and secondary intestinal ischemia. Transient hyperperistalsis and anal sphincter relaxation occur, thereby allowing passage of meconium. Meconium aspiration may occur before, during, or immediately after delivery as a result of fetal gasping. Meconium can produce a variety of clinical signs including mechanical airway obstruction (ball-valve effect) and regional air trapping, chemical pneumonitis and alveolitis, alveolar edema, and displacement of surfactant by free fatty acids in meconium, leading to decreased lung compliance, small airway obstruction, and focal atelectasis.[65–67] These events lead to increased pulmonary vascular and airway resistance and ventilation-perfusion mismatching. Meconium may also enhance the growth of bacterial species within the respiratory tract, resulting in secondary bacterial pneumonia. It may be difficult to differentiate meconium aspiration from bacterial pneumonia, especially if the birth was unattended. Occasionally, chronic placentitis is associated with both bacterial pneumonia and meconium aspiration.

304

305

If meconium has been aspirated into the pharynx, then gentle suctioning of the nasal and oral cavities is recommended. The ideal time to suction the airways is while the animal is still in the birth canal, before it has taken its first breath. If the foal shows signs of meconium aspiration below the vocal cords, nasotracheal intubation and careful, aseptic suctioning are recommended. Intranasal oxygen should be administered during suctioning. ABG analysis dictates what long-term respiratory and metabolic support is necessary. Mild to moderate hypoxemia can be treated with humidified intranasal oxygen (2 to 10 L/min). Severe hypoxemia with accompanying hypercapnia requires positive pressure ventilation (PPV) and is associated within increased mortality. If surfactant displacement and secondary atelectasis is contributing to hypoxemia, continuous positive airway pressure (CPAP) alone may improve oxygenation while avoiding any unnecessary increase in peak airway pressure. Exogenous surfactant administration has been advocated to treat the surfactant dysfunction, although efficacy data are lacking. Intravenous dimethyl sulfoxide (DMSO) (0.5 to 1 gm/kg) administered as a 10% solution may help reduce alveolar and interstitial edema. Systemic antibiotic therapy is recommended to prevent secondary bacterial pneumonia. Good airway hygiene and coupage are crucial.

A diagnosis of meconium aspiration is based on a history of meconium-contaminated amniotic fluid and a meconium-stained newborn. Radiographs typically show a ventrocranial distribution of pulmonary infiltrate characteristic of aspiration. Clear, brownish fluid may drip from the nose.

19.4.1.4

Milk Aspiration

Aspiration of milk into the lower airway may occur as a complication of a wide range of conditions. Most foals that aspirate milk also demonstrate nasal regurgitation of milk. Unfortunately the decreased sensitivity of the upper and lower airway to foreign material may make diagnosis of milk aspiration difficult. Aspiration can occur in foals with cleft palate, persistent DDSP, botulism, HIE, or generalized weakness resulting from sepsis or prematurity. Iatrogenic contamination of the airway can occur when bottle-feeding is forced or if the foal is too weak or sleepy to receive feeding. Substantial and sometimes fatal pneumonia can result from inappropriate placement of a nasogastric tube.

The diagnosis of milk aspiration is supported by historical data (nasal regurgitation of milk), physical examination findings (abnormal lung and tracheal sounds), and laboratory data (inflammatory leukogram, elevated fibrinogen, hypoxemia). Radiographic examination commonly reveals a heavy, perihilar, and/or ventrally located interstitial density with or without air bronchograms.

The treatment of milk aspiration involves long-term, broad-spectrum antimicrobial therapy and prevention of further contamination of the airway. The underlying cause should be pursued diagnostically and treated. This may necessitate the use of further diagnostic tests, including endoscopy and plain and contrast radiography. Enteral feeding through a nasogastric or esophagostomy tube is indicated until the underlying problem has been resolved. Persistent or intermittent DDSP in the neonate frequently resolves over time, but this may take weeks to months.

19.4.1.5

Pneumothorax[68] and Hemothorax

Pneumothorax is usually an iatrogenic sequela of PPV of diseased lungs, but it may occur spontaneously or as a result of birth trauma or from ruptured bullae within the lung parenchyma. During mechanical ventilation uneven alveolar ventilation leads to alveolar rupture and dissection of air into the interstitium. The air moves along bronchioles and other lung structures to pleural surfaces, forming blebs. This air may rupture into the pleural space. The condition should be strongly suspected if the respiratory condition suddenly worsens while an animal is being ventilated. Clinical signs may include respiratory distress, shift of cardiac point of maximum impulse, cyanosis, and hypotension. Although auscultation may reveal decreased breath sounds, it may be misleading because of the wide referral of breath sounds. Percussion is usually fairly unremarkable, unless the condition is very severe. Radiographs are indicated to confirm the diagnosis, but, if radiology is unavailable or the animal is very distressed, a direct needle aspiration is diagnostic and therapeutic.

Pneumothorax may be treated conservatively if no distress is associated with the air leak and the condition appears stable. Stress should be minimized. Chest tube insertion is indicated in human infants with continuing air leak, if underlying pulmonary disease is causing respiratory distress, and in those patients receiving mechanical ventilation. A trocar catheter is sterilely introduced into the chest cavity, and the catheter is secured, with the suture material crisscrossed tightly around the catheter. Suction is applied at −15 cm H_2O after confirmation of chest tube position by chest radiograph. Suction is discontinued when the tube has drained no air for 24 to 48 hours and when extrapulmonary air has been resolved radiographically for 24 to 48 hours. The tube may then be placed under a water seal for an additional 24 hours, and if no air accumulates the tube may be removed.

Hemothorax is occasionally noted in the large animal neonate. It has occurred secondary to unstable fractured ribs, with puncture of the lung parenchyma resulting in hemorrhage into the pleural space. Occasionally

hemothorax may remain undiagnosed until clinical signs of anemia, hypovolemia, or shock appear in the young animal.

19.4.1.6 Idiopathic or Transient Tachypnea in the Neonate

A syndrome observed in Clydesdale, thoroughbred, and Arabian neonatal foals has been the combination of fever and tachypnea. The condition appears to be more frequent during hot, humid weather conditions. The pathogenesis of the condition is unknown, but it is speculated that it results from a transient problem in central or peripheral control of thermoregulation and/or respiratory rate and pattern.

Affected foals are usually of normal gestation and experience a normal birth. Most display normal activity for a variable period after birth, with a sudden onset of clinical signs. Occasionally a foal may show mild signs of CNS derangement (e.g., lack of affinity for the mare, wandering). There are usually no signs of pulmonary abnormalities as assessed by thoracic radiographs or ABG analysis. Body temperature is variable among foals, ranging from 102° F to 108° F (39° C to 42.2° C). A generally poor response to antipyretics has been noted. The respiratory rate and breathing pattern often resemble panting (respiratory rate >80 breaths/min). The condition usually resolves spontaneously within a few days to weeks.

305

306

Before idiopathic tachypnea is diagnosed, it is extremely important to rule out a pneumonic process or other pulmonary abnormality, other forms of infection, metabolic acidosis, and other causes of an increased respiratory rate. Hematology, chest radiographs, and arterial blood gases should be within normal limits, and bacterial cultures should be negative.

Treatment is directed at controlling the body temperature; body clipping, alcohol baths, and maintenance of a cool environment are the most effective methods. If infection cannot be entirely ruled out, antibiotic therapy should be used.

19.4.1.6.1 Treatment of Respiratory Distress

It is beyond the scope of this book to provide detailed information on the respiratory support of the large animal neonate, and the reader is referred to other articles and texts for additional information on mechanical ventilation and other topics.[69–71] Oxygen therapy is extremely useful in the treatment of the large animal neonate with respiratory disease. The decision as to when to institute oxygen therapy is somewhat subjective and is based both on clinical signs and on blood gas analysis. Increased respiratory rate, labored respiration, increased intercostal and abdominal muscle activity, and restlessness are considered indications for a trial of oxygen therapy. A Pa_{O_2} <55 to 60 mm Hg in lateral recumbency is considered an objective indication for oxygen therapy, although many foals with a Pa_{O_2} of 50 to 55 mm Hg on room air that were recovering from pneumonia apparently did well and displayed no signs of hypoxia. If blood gas analysis is not available, clinical signs indicating a favorable response to oxygen therapy include a decrease in effort of breathing, decrease in respiratory rate, and a more comfortable-appearing animal. An absence of response may indicate a nonrespiratory origin of the clinical signs, severe lung pathology, a cardiac malformation resulting in right-to-left shunting of blood, or inadequate inspired oxygen concentration.

The inspired oxygen concentration is most easily increased by nasal insufflation using a bias flow of humidified oxygen. Although an oxygen-delivery mask can be used, its presence interferes with nursing or feeding, and it may be poorly tolerated by the alert foal. Depending on the severity of disease and size of the

individual, oxygen is initially delivered at a flow rate of about 5 L/min, and the response is noted. The catheter tip should be advanced into the nasopharynx, and the opposite end should be secured to the nostril using tape or sutures in active foals. The actual oxygen concentration delivered to the alveoli depends on several factors, including the position of the tube and the depth and rate of breathing. Oxygen therapy should be directed at maintaining a Pa_{O_2} of 80 to 100 mm Hg, and the flow rate should be adjusted according to blood gas results. Oxygen therapy should be on a continuous basis, and weaning from support should be done gradually. Transtracheal oxygen delivery may beneficial in larger foals, hypoxemic neonatal foals that have a very rapid, shallow breathing pattern, and foals with severe pulmonary disease that are unresponsive to nasal insufflation.[72] A percutaneous catheter system is placed using local anesthetic and is secured to the skin. The distal location of the catheter bypasses a substantial volume of dead space, and probably results in a higher alveolar oxygen concentration. One advantage of this method of oxygen delivery has been the ability to provide long-term oxygen therapy to unrestrained foals.[72]

Unfortunately, oxygen therapy is not effective in correcting hypoventilation, and if hypercapnia is progressive and accompanied by signs of increasing respiratory distress, some type of mechanical ventilatory support is usually indicated. This decision to provide mechanical ventilation must take into account several considerations, including the worth of the individual, the commitment of the owners, the facility and manpower availability, and the type of disease process present.

Regardless of the level of respiratory support provided, the importance of meticulous respiratory supportive technique cannot be overemphasized. Maintenance in sternal position, frequent turning from side to side, regular coupage, and use of proper suction technique are all very important components of respiratory support.

19.5 DISTENDED AND/OR PAINFUL ABDOMEN

Wendy E. Vaala

19.5.1 APPROACH TO DIAGNOSIS

The large animal neonate with a painful or distended abdomen can present a diagnostic challenge to the clinician. Medical and surgical causes of colic and GI disease in the foal include ileus and bowel distention associated with peritonitis, hypoxic gut damage and metabolic disturbances, enteritis caused by dietary changes, viral infections and bacterial pathogens, gastroduodenal ulcer disease (GDUD), impaction associated with ascarid infections, intussusception, thromboembolic disease, small intestinal volvulus, colon torsion, uroperitoneum, strangulating abdominal hernias, and congenital GI lesions. The clinical challenge is to distinguish medical from surgical lesions to permit rapid and appropriate therapy. Abdominal surgery in young foals, particularly neonates, is associated with increased morbidity and mortality and a higher incidence of intraabdominal adhesion formation when compared with surgery in mature horses.[73] Medical causes of GI disease such as enteritis and peritonitis carry an increased risk of generalized sepsis and death if the patient's cardiovascular status and metabolic parameters are not monitored and stabilized in a timely manner.

Box 19-1 lists some of the more common conditions associated with the acute abdomen in large animal neonates. Physical examination findings can be very similar between neonates requiring surgical intervention and those with only an infectious problem, such as enteritis. If abdominal distention is present, every effort should be made to identify its cause. Because the neonatal foal is considerably smaller than the adult, some of the diagnostic techniques routinely used in the adult (rectal palpation, assessment of shape of abdomen) are of limited value in

assessing the acute abdomen in the neonate. Bilateral, tympanitic distention of the paralumbar fossae is suggestive of generalized ileus or large bowel obstruction (e.g., meconium impaction). Other diagnostic aids including abdominal radiographs, transabdominal ultrasonography, abdominal ballottement, and transcutaneous abdominal palpation are not practical in the adult but are useful diagnostic tools in the newborn foal. Abdominal ultrasound is a critical diagnostic procedure in horses of all ages.

The approach to the neonate with a painful or distended abdomen should include a complete history, including any abnormalities noted during the perinatal period, the type and dose of any analgesics previously administered, and whether there is history of diarrhea in other foals or horses on the farm. The age of the foal helps determine the risk of certain conditions. Young foals less than 2 weeks of age are more likely to experience colic caused by meconium retention, peritonitis associated with generalized sepsis, hypoxic gut damage, uroperitoneum, and congenital deformities including lethal white syndrome (e.g., mesenteric aganglionosis), inguinal and scrotal hernias, and atresia of the anus or colon.[74–76] We have also seen increasing numbers of young foals with clostridial enteritis that are presented for treatment for colic. Older foals are more likely to suffer from intussusceptions, enteritis, gastroduodenal ulceration, and thromboembolic disease.[74,75]

Severe liver or renal failure

Severe hypoproteinemia

The neonate's age at the onset of abdominal distress also may provide diagnostic clues. For example, foals with meconium impaction or congenital GI malformations such as atresia coli tend to be presented for treatment during the first 12 to 36 hours of age, whereas foals with uncomplicated ruptured urinary tracts are usually presented at about 3 days, when the abdomen is visibly distended. The character, quantity, and frequency of defecation and urination should be determined. Surgical GI lesions such as intussusception and large colon displacement have occurred secondary to enteritis. On the other hand, in the early stages, enteritis alone can cause severe abdominal distention or severe pain, in the absence of diarrhea. NEC and clostridial enteritis can be particularly painful conditions. Most foals with ruptured urinary bladders display abnormalities in urination, but in some cases normal micturition has been noted. Reduction in urine output from a neonate with a distended abdomen is not pathognomonic for uroperitoneum. Urine volume is typically reduced as a result of dehydration

secondary to a variety of abnormalities, including GI disease.[77] The colic associated with uroperitoneum is not usually severe.

Assessment of the degree of pain being exhibited is an important part of the examination of the neonate with a distended abdomen. Foals more commonly show signs of abdominal discomfort than do calves. In a retrospective study of foals undergoing exploratory celiotomy, uncontrollable pain and severe abdominal distention were the primary reasons the animals were taken to surgery. Sever abdominal pain can also occur in foals with non-surgical lesions, such as sever enteritis, making the decision for surgical exploration difficult in some cases.[78] However, persistent tachycardia in a neonate with a heart rate in excess of 150 beats per minute (bpm) despite administration of analgesics and in the absence of fever is suggestive of a surgical GI lesion.

The degree of compromise to the cardiovascular and pulmonary systems should be assessed. A neonate with an abdominal crisis is often in need of immediate stabilization because of shock secondary to endotoxemia or hypovolemia. Exploratory celiotomy in neonates that receive inadequate presurgical supportive therapy is associated with a number of complications, including poor tolerance to anesthesia. The degree of respiratory compromise secondary to the abdominal problem should also be considered, particularly if the animal is a surgical candidate. For example, foals with long-standing uroperitoneum may have pleural effusion and pulmonary abnormalities as well as serum electrolyte abnormalities, all of which may predispose to anesthetic problems (hypoxemia, hypercapnia, cardiac arrhythmias).

It is very important to establish the likelihood of generalized or localized infection such as enteritis. Generalized sepsis can interfere with the function of many organ systems, including the GI tract. The first signs of enteritis are often severe abdominal distention and colic, with diarrhea becoming apparent a few hours to days later (Fig. 19-3); the severity of these signs may warrant surgical exploration of the abdomen. Leukopenia may be observed in foals with septicemia, enteritis, peritonitis, and surgical GI lesions. An unexplained metabolic acidosis may also indicate impending enteritis.

Additional information on the physical examination of the abdomen and GI tract can be found in Chapter 17. It is difficult to distinguish fluid accumulation in the large colon from accumulation in the peritoneal cavity using physical examination alone, and additional diagnostic procedures are usually required to distinguish the two (see later). In general, nasogastric intubation in the neonatal foal does not seem to be as useful a diagnostic technique as it is in the adult horse. Gastric reflux can be difficult to obtain, even if the stomach appears markedly distended on radiographs, and a moderate amount may be obtained in cases of ileus. If large volumes of reflux are obtained, however, obstructive disease (e.g., of the pylorus and small intestine) is considered more likely.[78]

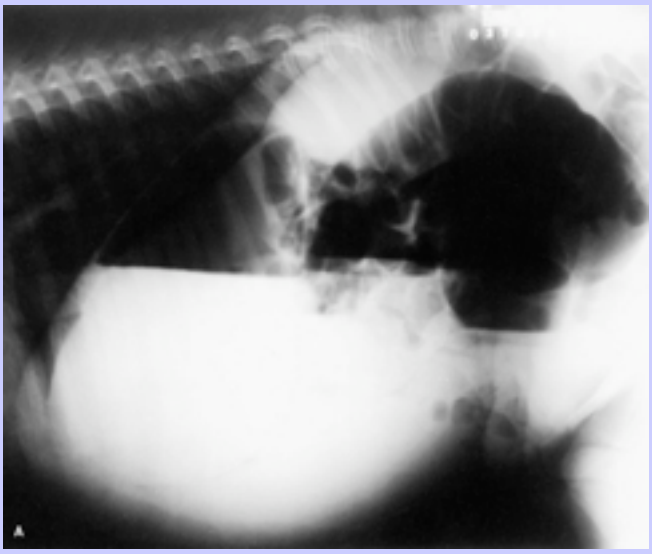
Neonates with enteritis, uroperitoneum, and other abdominal problems can have markedly deranged serum electrolyte concentrations (hyperkalemia, hyponatremia, and metabolic acidosis are typical). Failure to recognize the severity of these abnormalities or adequately treat them can result in the death of the patient.

Abdominal radiographs can be very helpful in identifying segments of the intestinal tract that are distended, fluid in the peritoneal cavity, and the composition of ingesta in the GI tract (e.g., sand, meconium) (Figs. 19-4 and 19-5). A good knowledge of normal radiographic anatomy of the intestinal tract is important for accurate interpretation (Fig. 19-6). Adequate radiographs are obtained in foals up to 250 kg if available radiograph equipment includes a grid, rare earth screens, and sufficient milliampere-second (mAs) (5 to 28) and kilovolt peak (kVp) (75 to 95) levels. With experience in viewing normal and abnormal abdominal radiographs, the likelihood of an obstructive lesion versus simple ileus can be established in some but not all cases. The presence of erectile, distended loops of small intestine is most consistent with a diagnosis of obstructive disease. Intramural gas is suggestive of NEC. It can be very difficult to differentiate large colon torsion or displacement

307 308 308 309

from simple gas and fluid distention secondary to ileus. Contrast radiography can help to define the location and nature of GI problems such as duodenal stricture and abnormalities of the small colon or rectum. Further details on the radiographic diagnosis of abdominal disorders are contained in other articles. [78a,78b,78c,78d]

Fig. 19-3 **A**, Abdominal radiograph (standing) of a 48-hour-old foal that was presented with meconium impaction and a distended abdomen. The foal also had a metabolic acidosis, hypoglycemia, and leukopenia. Note the gaseous distention of the large intestines, which was suggestive of ileus and possibly obstruction. **B**, Standing abdominal radiograph of the same foal 24 hours later after passage of diarrhea. Following removal of the meconium, profuse bloody diarrhea was observed, suggesting enteritis. With passage of the diarrhea, gas distention resolved.



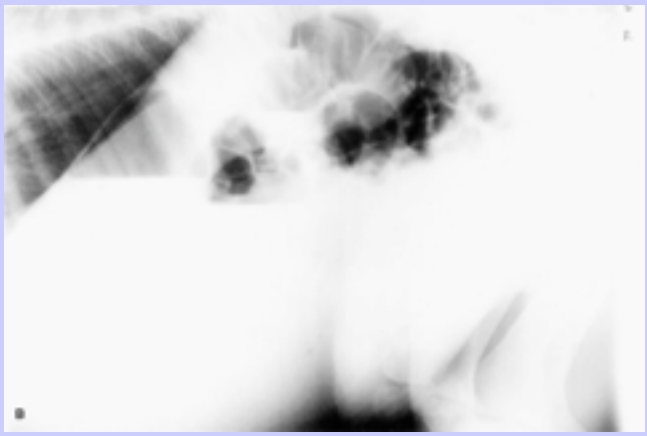


Fig. 19-4 Sand accumulation in the ventral colon of a 1-month-old foal with chronic diarrhea and intermittent colic.

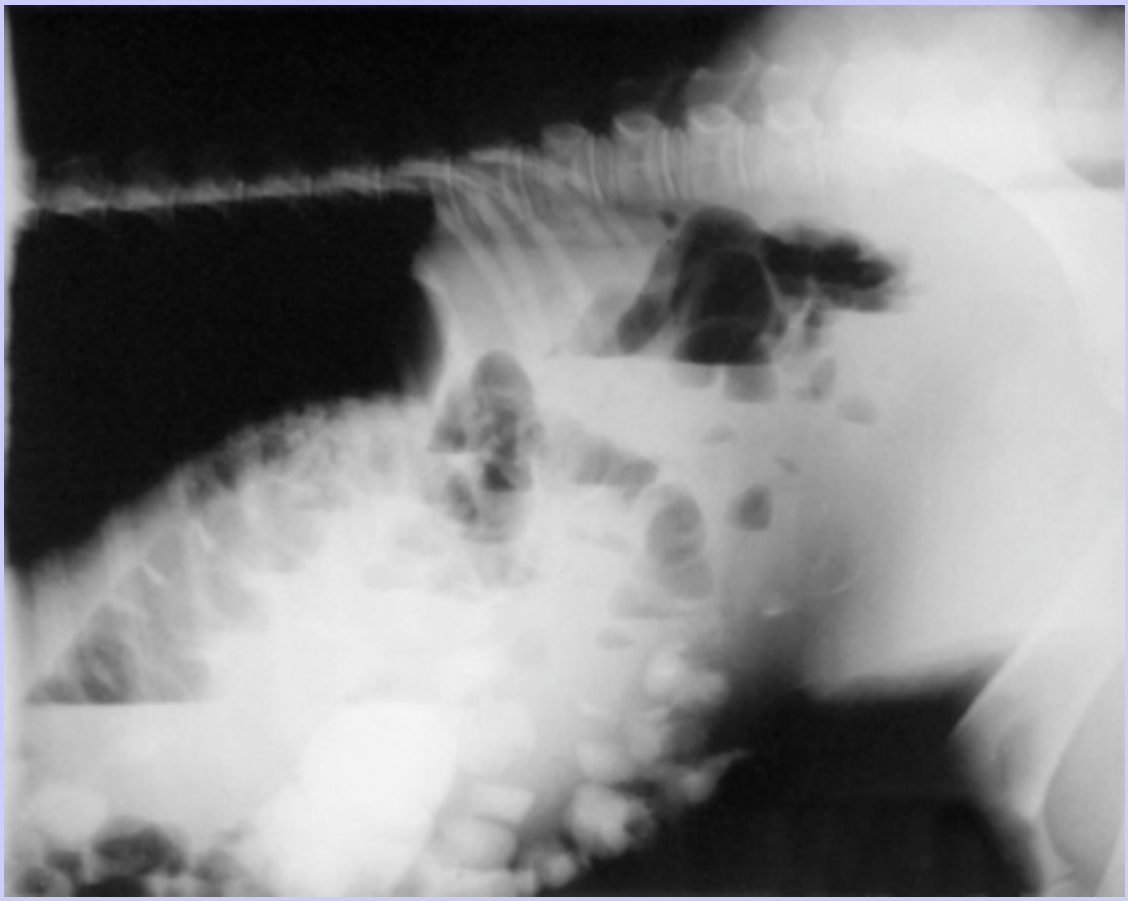

Fig. 19-5 Abdominal radiograph (lateral recumbency) of a 7-hour-old miniature horse foal with atresia ani, showing meconium packed into a gas-distended large colon. The extent of the atresia proximally from the anus is not visible.

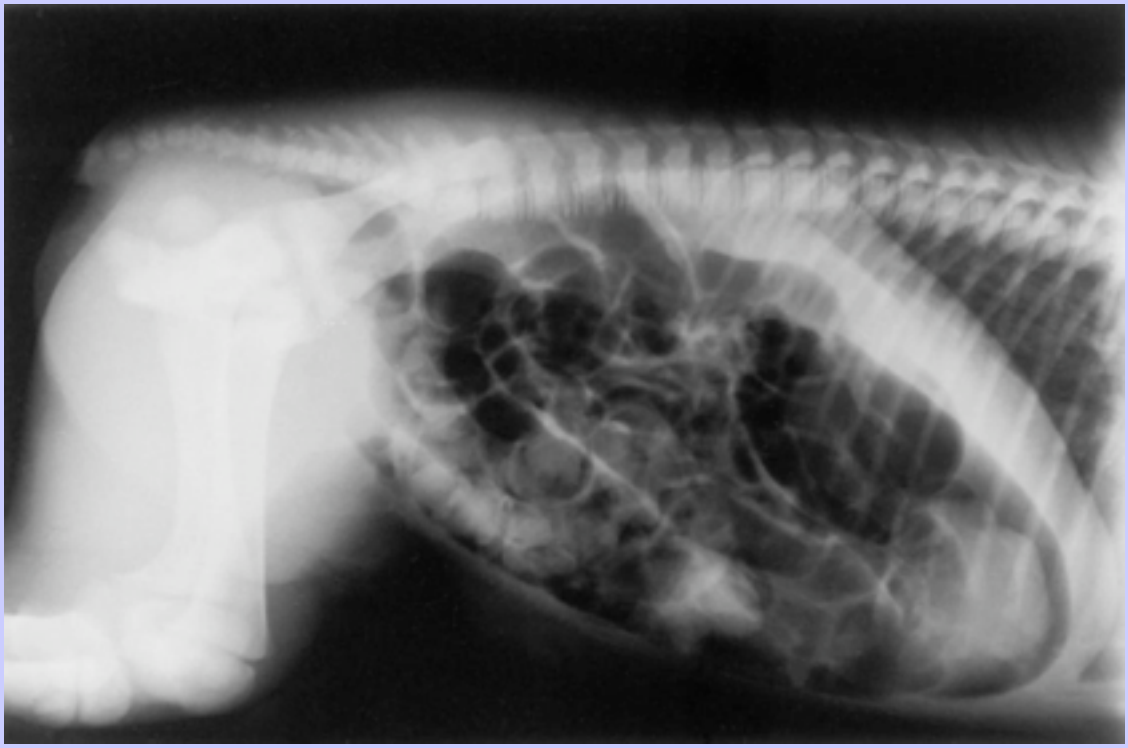

Abdominal ultrasonography can be of value in diagnosing certain conditions that may be contributing to a distended or painful abdomen, including fluid-distended small and large intestine, ascarid impaction, intussusception, colonic impaction, uroperitoneum, and abnormalities of the umbilical vessels and urachus. Ultrasonography also permits characterization of small intestinal motility, distention, and bowel wall thickness. Healthy foals have flaccid, fluid-filled loops of small intestine. The presence of rounded, distended loops of small intestine is suggestive of an ileus, enteritis, or possible small bowel obstructive disease. The location, amount, character, and echogenicity of free peritoneal fluid can also be determined (Fig 19-7).[61,79,80] A large accumulation of peritoneal fluid with increased echogenicity (or fibrin) is suggestive of peritonitis, whereas an excessive volume of hypoechogenic peritoneal fluid is suggestive of uroperitoneum.

In our opinion, except in a couple of specific conditions, peritoneal taps are of limited value in diagnosis of the acute abdomen in the neonate. Extreme caution should be exercised to avoid perforating the bowel while attempting to acquire a sample of peritoneal fluid, particularly if intestinal distention is present. The intestine of the neonate is easily ripped by inadvertent perforation with a needle or teat cannula, even if the neonate is well restrained. It is probably safest to perform the procedure using ultrasonography to image the fluid pocket and the needle position. Foals with uroperitoneum are the ideal candidates for abdominocentesis. Clear yellow, urine-like

peritoneal fluid is easily and safely obtained in these patients because the excessive volume of peritoneal fluid allows the abdominal viscera to float well above the ventral floor of the abdomen.

Fig. 19-6 Normal standing abdominal radiograph in a neonatal foal. Note the prominent fluid line in the stomach and the presence of gas in various portions of the tract.

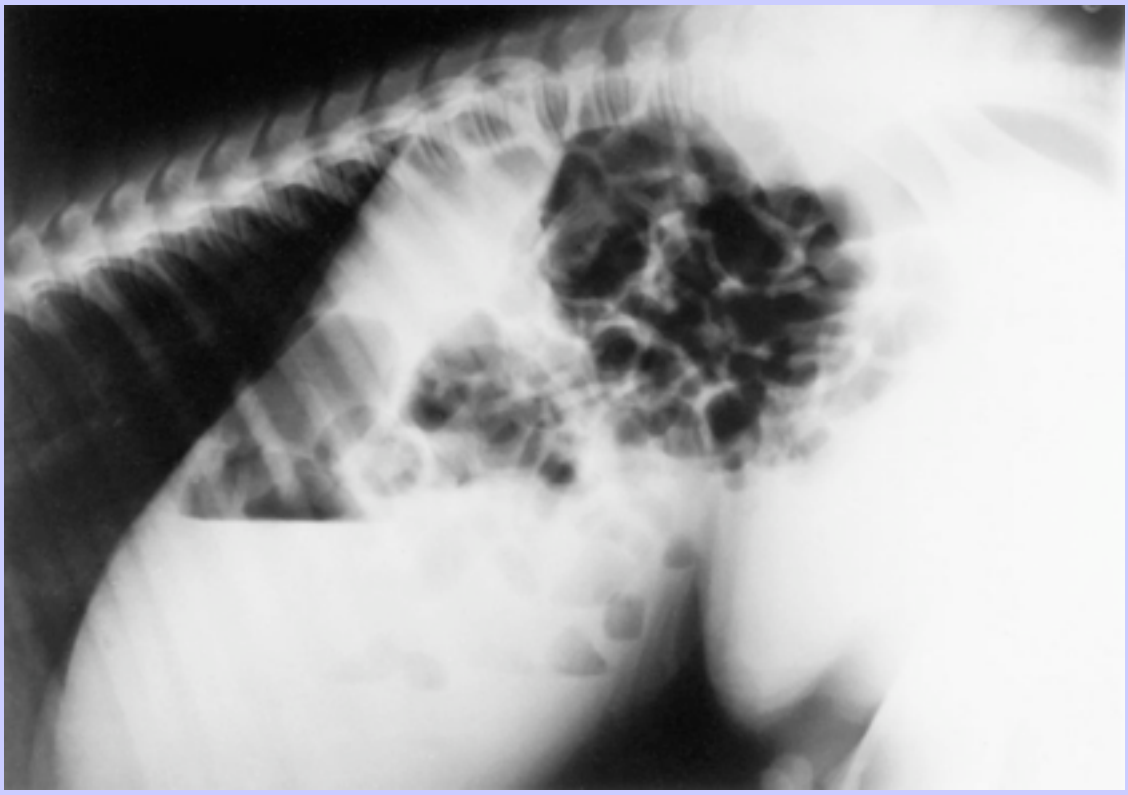

Fig. 19-7 Ultrasound view of the caudal abdomen of a 24-hour-old premature foal with a torn urachus, showing (from top to bottom) the ventral abdominal wall, free abdominal fluid (black), the urinary bladder (oval structure to the right), and small intestinal loops (cross-sectional view).

Normal peritoneal fluid is similar to that in the adult, except that the normal WBC count is lower (1500 cells/µl or less).[81] Cytologic examination should also be performed to determine the cell types present and to detect the presence of bacteria and toxic neutrophils (suggesting peritonitis) and fecal material (suggesting either

inadvertent gut tap or bowel rupture). The total protein and WBC count may be elevated in a variety of conditions. These include severe enteritis; urachal, umbilical, or severe bladder infection; and primary peritonitis, in addition to conditions in which there is ischemic bowel requiring surgical resection. On the other hand, as in the adult, normal peritoneal fluid has accompanied a number of surgical intestinal lesions, such as large colon displacement. Therefore peritoneal fluid analysis is of limited value in distinguishing the surgical patient but can be useful in the diagnosis of peritonitis. In addition, peritoneal fluid analysis usually results in a straightforward diagnosis of uroperitoneum. In virtually all cases of uroperitoneum observed to date, peritoneal creatinine level was greater than the serum level (usually >2:1). Also, the acquisition of free-flowing blood from the abdominal tap usually allows a diagnosis of hemoperitoneum.

Endoscopy of the upper and lower GI tract of the foal can be performed if appropriately sized equipment is available (8 to 10 mm OD, 180 to 250 cm long).[77] The esophagus and stomach can be examined for erosion, ulceration, perforation, and other abnormalities. Suspected impactions or malformations of the rectum and small colon can also be examined.[74]

In summary, accurate identification of foals with acute abdominal problems requiring surgery can be very difficult even with the use of ancillary diagnostic procedures, and mistakes are commonly made because there are no clear-cut and consistent differences between medical and surgical cases. Findings suggestive of the need for surgical exploration include severe and unrelenting pain and persistent tachycardia.

311

19.5.2 SPECIFIC CONDITIONS

19.5.2.1 Meconium Impaction

Meconium impaction is the most common cause of colic in the newborn foal. This condition is more common in colts because of the narrow pelvic canal. Many foals show some degree of straining and discomfort while passing meconium, but in most instances it is passed uneventfully by 24 to 48 hours of age. The meconium most commonly becomes impacted in the rectum or small colon. The clinical signs associated with meconium impaction in the otherwise normal foal include repeated attempts to defecate, straining with the back arched, swishing of the tail, and restlessness. Nursing stimulates defecation through an oral-anal reflex, so signs of discomfort may appear shortly after each milk meal. If left untreated, meconium impactions lead to varying degrees of abdominal distention. The foal's abdomen becomes gas distended, with tympany detected over the paralumbar fossa. Digital examination often reveals a rectum packed with hard fecal balls. Occasionally, the impaction is located more proximally (large or small colon) and radiography or ultrasonography is required for diagnosis.

Low doses of analgesics such as dipyrone (10 to 22 mg/kg IV), flunixin meglumine (0.25 to 1 mg/kg IV), and butorphanol (0.01 to 0.1 mg/kg IV) may be required to prevent self-trauma during colicky episodes. Xylazine may exacerbate gut stasis and can cause respiratory depression, and it should be used with caution in newborn foals. A gravity enema with mild soap and warm water or a commercial Fleet enema usually results in prompt evacuation of the meconium. Refractory meconium impactions may respond to acetylcysteine retention enemas.[82] The supplies and procedure for a retention enema are as follows: Mix together 150 mL water, 6 g of acetylcysteine powder, and 20 g of sodium bicarbonate (baking soda). Insert a well-lubricated 12 or 14 French, cuffed Foley urinary catheter into the rectum and inflate the cuff. Slowly infuse 120 to 180 mL of the retention enema solution. Plug the end of the catheter. Tape the catheter loosely to the foal's tail. Leave in place a minimum of 15 minutes, then deflate the cuff and remove the catheter. This procedure can be repeated several times. Care must be taken to avoid traumatizing the rectal mucosa by stiff tubing or multiple enemas

with harsh detergents. Clinical signs associated with meconium impaction in the compromised foal may be absent. In asphyxiated or premature individuals that are receiving little or no enteral feeding, meconium may remain in the large colon for days, gradually forming into hard concretions that are diagnosed by palpation or radiographs or at postmortem examination. In these cases the routine administration of an enema is often ineffective in mobilizing the impaction because it is high in the large colon. Additional therapy includes intravenous fluids, oral fluids, and laxatives (60 to 120 mL of mineral oil with ½ to 1 oz of psyllium, 60 to 120 mL of milk of magnesia). If the gas distention becomes severe, transcutaneous bowel trocarization can be pursued. We avoid the use of Dioctyl sodium sulfosuccinate (DSS) as an oral cathartic because it can cause excessive irritation, resulting in diarrhea and colic. Analgesics may also be helpful in controlling the neonate's discomfort and in reducing the risk of self-trauma. Although most meconium impactions can be successfully treated with aggressive medical therapy, those few foals that are refractory to treatment or display uncontrollable pain are candidates for surgical intervention.

19.5.2.2

Uroperitoneum

Uroperitoneum is a relatively common cause of abdominal distention and depression in the neonatal foal. The condition predominates in males but may occur in females as well. Uroperitoneum may be congenital or acquired. The congenital form occurs as a result of failure of the dorsal wall of the bladder to close during development.[83] The most common cause of uroperitoneum is a ruptured urinary bladder, but other sites in the urinary tract may also leak, including the ureters, urachus, and urethra. Most cases of ruptured bladders are presumed to occur during parturition because of external pressure on a distended bladder. This form occurs most commonly in colts. Uroperitoneum can also occur secondary to ischemic necrosis or infection of the urinary bladder or urachus in the compromised foal.[78] Critically ill, recumbent foals may rupture their bladders while being lifted and turned with a full bladder or as a result of chronic overdistention associated with the generalized disease state. Foals with botulism may also rupture their bladders secondary to bladder atony and chronic overdistention. Older foals of either sex may experience bladder rupture secondary to focal infection of the umbilical arteries and/or urachus, or ischemic necrosis of the apex of the bladder.

Clinical signs of uroperitoneum are rarely noticed before 48 to 72 hours of age, particularly if the foal is not being watched closely. The first signs may be urinary incontinence or frequent attempts to urinate, with only small amounts voided. Sometimes, particularly in those animals that experience rupture sometime after birth, there is a history of a period of normal urination, which at some point stopped or became abnormal. Loss of suckle, mild colic, and increasing abdominal distention are usually accompanied by worsening depression and increasing heart and respiratory rate. If the condition is allowed to persist, foals become increasingly weak and dyspneic and may be presented in cardiovascular collapse. Fillies with ruptured ureters have been reported to have a characteristic protruding perineum, presumably as a result of retroperitoneal accumulation of fluid.[84]

Laboratory findings commonly associated with uroperitoneum are elevated serum creatinine and blood urea nitrogen (BUN), hyperkalemia, hyponatremia, hypochloremia, and metabolic acidosis. These changes are probably a result of the normal diet of the foal (milk being relatively high in potassium [25 mEq/L] and low in sodium [12 mEq/L]) and the third spacing of urine in the peritoneal cavity. With urine potassium concentration relatively higher than serum levels, and with urine sodium concentration lower than serum levels, the net effect of partial equilibration of serum with peritoneal fluid across a semipermeable membrane is hyponatremia and hyperkalemia, along with an inability to excrete the waste products of metabolism. Hyperkalemia may be severe enough to induce potentially fatal bradyarrhythmias. In hospitalized foals that developed uroperitoneum as a secondary complication, these typical electrolyte abnormalities are not consistently observed. Because most of those foals were receiving replacement intravenous fluids (high in

sodium, low in potassium) and very little milk, it was theorized that intake has a great influence on the electrolyte abnormalities associated with uroperitoneum.[85] On the other hand, the electrolyte abnormalities typically associated with uroperitoneum are not pathognomonic for that disorder. Foals with renal failure, blocked urethra, white muscle disease, and enteritis have shown the same electrolyte changes.

A diagnosis of uroperitoneum often can be made quickly using transabdominal ultrasound and a 5- or 7.5-MHz transducer to visualize large volumes of free, nonechogenic fluid within the abdomen and a small, irregularly shaped, collapsed bladder. Abdominocentesis usually produces a free flow of peritoneal fluid that has a low cell count, low specific gravity, and at least twice the creatinine concentration of peripheral blood. If the creatinine is the same in both serum and peritoneal fluid, other explanations for the clinical signs should be investigated. The WBC count, total protein, and cytology of the fluid should also be determined. Most uncomplicated cases of ruptured bladders have fairly normal values for peritoneal fluid. In some cases, however, an increased WBC count and total protein and the presence of bacteria may suggest peritonitis. This may be a result of the urine in the abdomen, but more commonly there is a primary ongoing infectious problem (necrotic urachus or bladder, enteritis), and the prognosis becomes worse. If laboratory facilities are not available, new methylene blue can be injected into the bladder using a urinary catheter, and a few minutes later a sample of peritoneal fluid should have a blue discoloration if a ruptured bladder is present. However, this technique may not allow detection of other causes of uroperitoneum such as a ruptured ureter or distal urachus. Positive contrast cystography using a 10% solution of water-soluble media may be helpful in detecting the location of the urinary tract leakage. The ability to obtain urine on catheterization of the urinary bladder does not rule out uroperitoneum. Hematology and blood cultures should be performed to detect primary or secondary sepsis.

311

312

Treatment of uroperitoneum is surgical repair. However, the foal with uroperitoneum should not be rushed to surgery without first carefully stabilizing it. Serum electrolytes and blood gases should be run to determine the extent of hyperkalemia, hyponatremia, and acidosis present. Although the total amount of water in the body is usually grossly increased by the peritoneal accumulation of urine, effective circulating volume may be drastically reduced. If the eyeballs are sunken and the pulse quality and capillary refill time are poor, aggressive fluid therapy is indicated to support the circulation. This is best performed by concurrently removing as much fluid as possible from the abdomen with a teat cannula, 14G catheter, or peritoneal dialysis catheter to avoid worsening fluid overload and respiratory distress. The fluids of choice to treat the typical electrolyte alterations associated with uroperitoneum are saline, dextrose, and possibly sodium bicarbonate solutions, depending on the degree of acidosis present. In most instances continuous dextrose infusion is effective in decreasing the serum potassium level to an acceptable level, but values should be rechecked before anesthesia is induced. Insulin and dextrose may also be used to treat hyperkalemia, but the patient must be monitored for hypoglycemia. One suggested regimen is regular insulin at 0.1 to 0.2 U/kg subcutaneously (SC) or IV accompanied by a continuous intravenous dextrose infusion (4 to 8 mg/kg/min). Some individuals also have pleural fluid accumulation and atelectasis secondary to the abdominal distention, so oxygenation and ventilation during and after surgery should be closely monitored. Broad-spectrum antibiotics should be started immediately after samples are taken for culture if infection is suspected.

The prognosis for uncomplicated ruptured urinary bladders is usually good (>80% survival), provided the animal is stabilized before anesthesia. The presence of concurrent septicemia carries with it a considerably poorer prognosis.[85] In one retrospective study among foals with uroperitoneum, 100% of those foals with a negative sepsis score lived and only 57% of foals with a positive sepsis score survived.[85]

19.5.2.3

Gas or Fluid Accumulation in the Gastrointestinal Tract: Ileus

Abdominal distention and colic secondary to excessive gas and/or fluid accumulation in all or a portion of the GI tract are common complications in the compromised neonate undergoing intensive care. The exact mechanisms responsible for the presumably altered GI motility are not well defined. Ileus is associated with the absence of intestinal sounds, abdominal distention, and intolerance of oral feeds characterized by gastric reflux. Auscultation of reduced GI borborygmi does not always correlate with the degree of intestinal compromise and decreased motility. Transabdominal ultrasonography helps identify absence of intestinal motility and the location and degree of intestinal distention. Ileus and the attending abdominal distention can cause severe colic and can induce respiratory distress in a weak or premature foal with preexisting pulmonary compromise.

Metabolic and infectious causes of ileus in the foal include hypokalemia, hypocalcemia, hypoxic-ischemic bowel injury, bowel obstruction, peritonitis, enterocolitis, and endotoxemia. Hypokalemia is associated with anorexia, diarrhea, and renal loss. Hypocalcemia is associated with prematurity, decreased dietary intake, excessive bicarbonate administration, diuretic therapy, and those conditions such as asphyxia, toxemia, and sepsis that stimulate release of cortisol and catecholamines. Peripartum hypoxia results in a preferential decrease in blood flow to the gut and kidneys. Poor perfusion of the intestines leads to varying degrees of mucosal damage and decreased motility. Severely damaged bowel requires a period of gut rest to allow healing to occur before oral feeds are resumed. Premature resumption of enteral feeding is associated with colic, maldigestion, diarrhea (often bloody), and translocation of intraluminal bacteria across damaged bowel wall into the bloodstream. Some of the more common causes of bowel distention in the neonate include meconium retention, intussusception, ascarid impaction, and small intestinal volvulus. Peritonitis may be associated with intraabdominal abscessation, severe enteritis or GDUD, and generalized septicemia. The most common causes of enteritis in foals include rotavirus, *Clostridia* species, *Salmonella* species, and dietary changes. Endotoxemia is usually part of generalized septicemia. Chronic bowel distention, regardless of the cause, further impedes return of normal gut motility. In the foal, aerophagia, particularly in the struggling or hypoxic neonate, often results in gas distention that is not easily removed through a nasogastric tube, because gas tends to move quickly through the GI tract (Fig. 19-8). Abdominal distention is also commonly observed during mechanical ventilation in the foal and as a result of overfeeding in the calf. Foals with botulism are often intolerant of enteral feeding, probably because of altered GI motility. Use of certain milk replacers can result in bloat, colic, and diarrhea, even in the apparently healthy orphan neonate. Discontinuation of or a decrease in the amount of enteral feeding and, if possible, increased activity of the patient usually result in resolution of the problem.

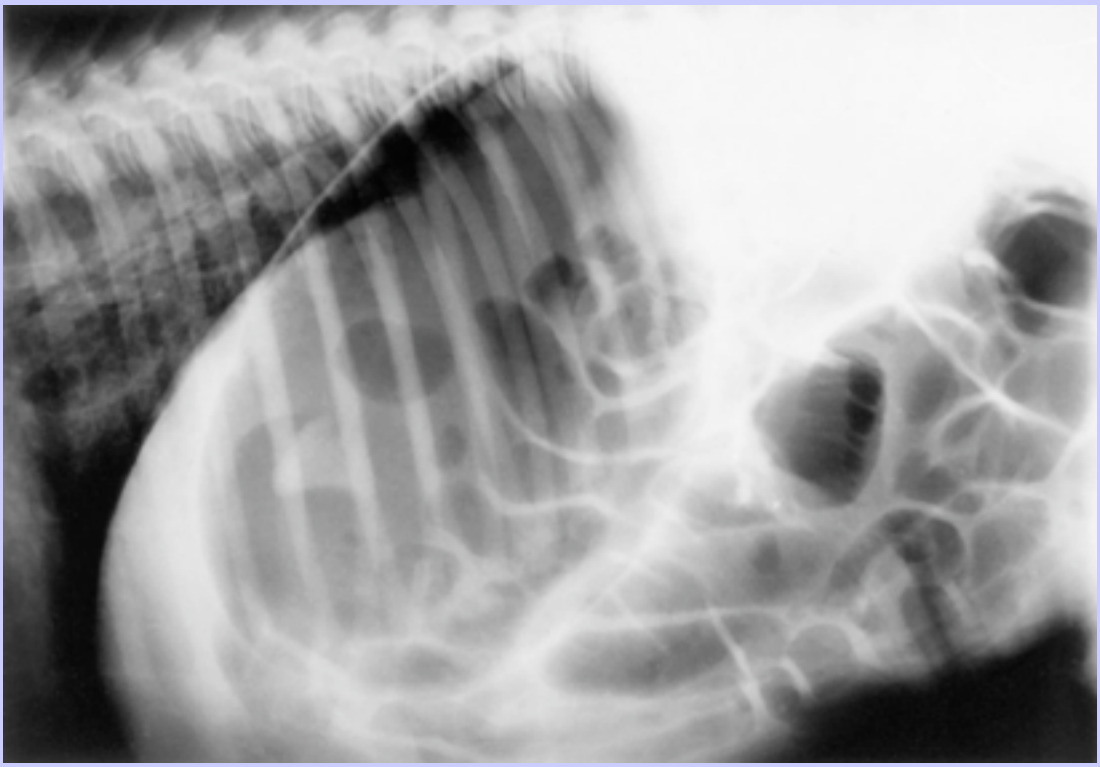
Abdominal radiographs reveal gas-distended loops of small or large intestine and may identify bowel obstruction. Sonographic examination permits evaluation of bowel wall thickness, peritoneal fluid volume and echogenicity, gut patency, intramural gas accumulation, location and degree of intestinal distention, and presence or absence of motility. An abdominal sonogram should be performed to rule out the presence of an intussusception or other obstructive lesion before any prokinetic therapy is initiated.

Management of ileus includes nasogastric decompression, cessation or reduced volume and frequency of enteral feeds if gastric reflux is present, parenteral alimentation if enteral feeding cannot be maintained at a rate of at least 10% of body weight per day, enema administration to relieve distal meconium or fecal retention, correction of any underlying electrolyte abnormalities, exercise for ambulatory foals, and judicious use of prokinetic agents. The gut atrophies without enteral feeding. Glutamine and butyrate are essential fuels for the small and large bowel respectively and have been added to enteral formulas for people and some oral

312
313

fluid replacement formulations for animals to help maintain and restore enterocyte health.[86] Prokinetic drugs should not be used when bowel obstruction or compromised bowel integrity is suspected. Prokinetic agents that have been used include metoclopramide, bethanechol, and erythromycin. There have been anecdotal reports of small intestinal intussusception after prokinetic use in neonatal foals.

Fig. 19-8 Marked gastric and generalized small intestinal gas distention in a septic, collapsed, 3-day-old thoroughbred colt. There is no evidence of obstruction. The patient was treated with supportive therapy and recovered.



19.5.2.4

Surgical Gastrointestinal Lesions

Most types of displacement, torsion, volvulus, and entrapments that occur in the adult horse may also occur in the neonatal foal, although probably at a lower frequency (Fig. 19-9). Large colon displacement, intussusception, and small intestinal volvulus have also been observed secondary to enteritis and colitis.

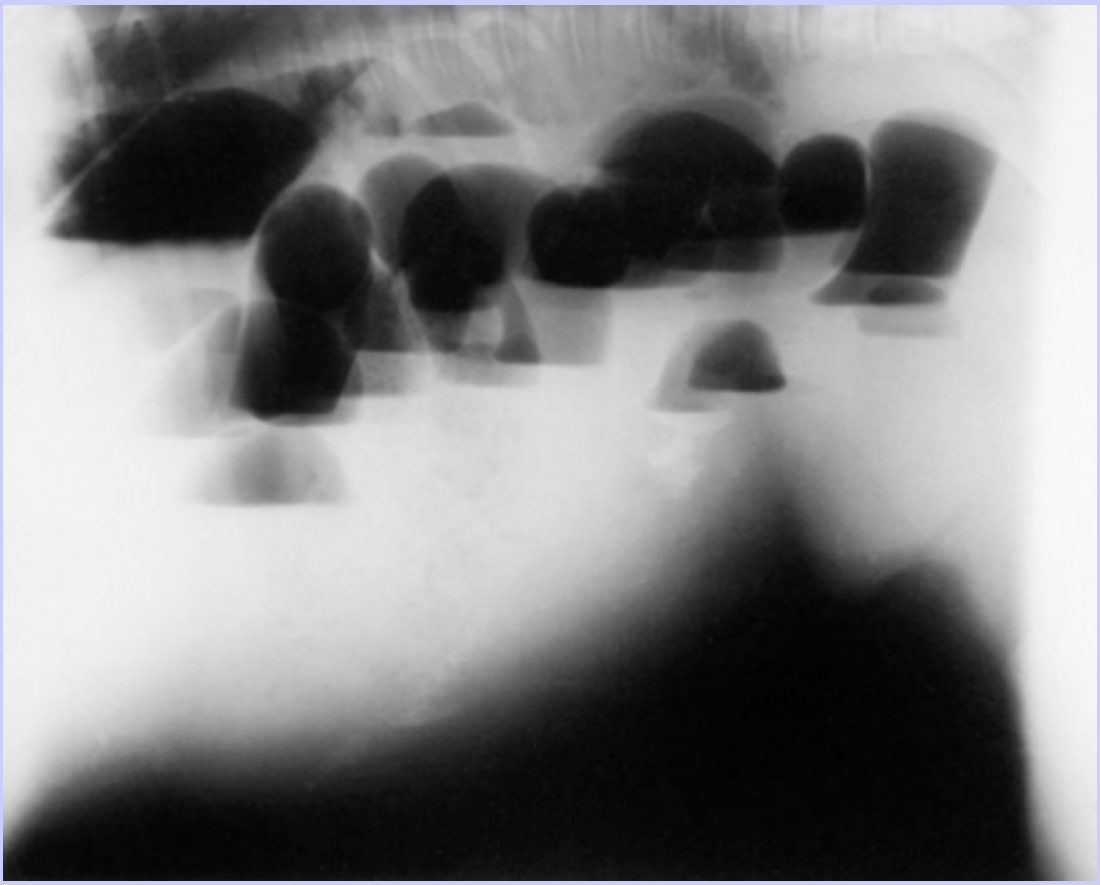
Surgical correction of congenital GI defects may be attempted. Atresia ani, atresia recti, and atresia coli have been well documented in the foal, and intestinal aganglionosis has been observed in association with recessive lethal white foals, which are usually the products of mating between two overo paint horses.[76] Acute colic, progressive abdominal distention, and lack of meconium staining after repeated enemas have been the most common findings in newborn foals with atresia coli. Barium enemas may be of use in identifying foals with a short small colon but may also be misleading.[87] Surgical exploration of the abdomen offers definitive

diagnosis of the severity of the malformation and the possibility of correction, but the owner should be informed before surgery of the high frequency of inoperable lesions and the high failure rate after reattachment.[87] Before any surgery is contemplated, a thorough physical examination should be performed to identify any other congenital malformations. Surgical correction of atresia ani is often successful, particularly if the atresia is limited only to a persistent membrane blocking the anus and the anal sphincter is normal. The prognosis for atresia coli is guarded. Poor intestinal motility, technical difficulties of attaching bowel segments that are so different in size, anastomosis breakdown, and peritonitis after surgery are common complications.[87] An inguinal hernia is another congenital lesion occasionally requiring surgical intervention. Such hernias occur in colts and may be caused by compression during parturition. Most congenital inguinal hernias are handled conservatively because the condition is often self-limiting by the time the foal is 3 to 6 months old. Treatment includes daily manual reduction of the hernia and frequent observation to detect possible bowel strangulation. Indications for surgical intervention in foals with congenital hernias include rupture of the common vaginal tunic, persistent colic, severe edema of the prepuce and scrotum, and trauma to the skin overlying the hernial sac. Surgical hernias are difficult to reduce manually, and loops of intestines are often palpable in the subcutaneous tissues of the scrotum and medial thigh.[88] Unilateral castration is usually performed on the affected side.

Other GI lesions in foals that may require an exploratory laparotomy include intussusception, small or large intestinal volvulus, and mechanical obstruction (e.g., food or ascarid impaction, phytobezoar, fecalith). Intussusceptions are reported in young horses less than 3 years of age. An intussusception is formed when one segment of intestine and its mesentery invaginates into the lumen of the adjacent bowel immediately aboral to it. The invaginated segment is called the *intussusceptum*, and the enveloping segment is called the *intussuscipiens*. Small intestinal intussusceptions can involve the jejunum, ileum, or ileocecal junction. Other sites of obstruction include cecocecal and cecocolic junctions. Intussusceptions are most common in foals less than 6 weeks old.[89]

Causes of intussusception include segmental motility differences (e.g., a hypermotile section of bowel adjacent to an atonic segment of bowel) and local changes in the bowel wall (e.g., abscessation). Causes of altered peristalsis include enteritis, heavy ascarid infestation, mesenteric arteritis, and sudden dietary changes.[90] Changes in the bowel wall have included granulomas, papillomas, and intramural leiomyoma. *Anoplocephala perfoliata* has been associated with ileocecal intussusceptions. Clinical signs include varying degrees of discomfort depending on the site of obstruction and its duration. Abdominal pain can be severe but is often low grade and intermittent, accompanied by decreased manure production. Ultrasonography is a useful diagnostic aid. Sonographically the cross-sectional view of the intussusception reveals a target-like pattern with a thick hypoechoic rim. The outer rim is created by severe edema of the entering and returning bowel walls of the intussusceptum.

Fig. 19-9 Standing abdominal radiograph of a 3-week-old foal that was presented with signs of severe pain. Note the multiple, erectile loops of distended small intestine with fluid lines. Obstructive disease was suspected. On surgical exploration of the abdomen, obstructing adhesions secondary to a previous surgery were found.



Treatment involves surgical exploration. Early cases can be manually reduced, followed by surgical resection. Because of the ileum's tenuous blood supply and the inaccessibility of the ileocecal junction, intussusceptions involving the ileum are usually treated with a side-to-side jejunostomy or ileocecostomy. Ileoileal intussusceptions have been reported to have a better prognosis than jejunal or ileocecal intussusception. Foals that have multiple sites of intussusception have a poor prognosis.

Volvulus may involve the small or large intestines. Small intestinal volvulus is the most common, especially among foals between 2 and 4 months of age. Signs include abdominal distention, gastric reflux, persistent tachycardia, severe pain, and sonographic evidence of uniform, severe bowel distention with bowel wall edema (>3 to 4 mm) and absence of motility. As expected, survival is poorer following correction of strangulating versus nonstrangulating lesions. Strangulating lesions of the small intestines are associated with poor survival compared with large intestinal lesions and have a higher incidence of fatal complications.

Parasitic migration and abrupt dietary changes are among conditions thought to predispose to volvulus development.

Surgical colic in foals carries a poorer long-term prognosis than in adult horses. One study[91] examined the survival rate among 67 foals <150 days of age that underwent colic surgery. The most common lesions requiring a celiotomy were small colon impaction, large colon impaction, jejunal volvulus, and ascarid impaction. A poor prognosis was associated with strangulating lesions. Foals less than 14 days of age experienced more early postoperative complications and suffered poor long-term survival because of adhesion formation. Only 25% of foals less than 14 days of age survived in the short term compared with a survival rate of 71% in foals older than 14 days of age.

Another study[92] examined the outcome among 119 young horses less than 1 year of age that underwent exploratory celiotomy. Among all foals the most common cause for surgery was small intestinal strangulation. Uroperitoneum and meconium impaction were the most common conditions in neonatal foals, and intussusception and enteritis were more common among older foals. Significant elevations in packed cell volume (PCV) (37% to 54%), heart rate (80 to 134 bpm), nucleated cell counts, total protein in peritoneal fluid (3.1 to 32.8 × 10^3/μL, 2.9 to 4.9 g/L), and rectal temperature (38.2° C to 39.2° C) were observed in nonsurvivors compared with survivors. Nonsurvivors had significantly decreased serum bicarbonate, chloride, sodium, and venous pH values. Thirty-three percent of foals that survived surgery had evidence of intraabdominal adhesions.

19.5.2.5

Necrotizing Enterocolitis

NEC has been described in equine neonates.[93] It is a syndrome of acute intestinal necrosis.[94] In human infants, prematurity is the single greatest risk factor, with only a small percentage of affected infants being full term. The causes of NEC are not well defined, but predisposing factors include ischemic hypoxic gut injury, presence of intraluminal bacteria, and enteral feeding. After GI ischemia, mucosal cell metabolism diminishes and the protective mucous layer is lost. This allows enzymes to break down the mucosal barrier, and intraluminal bacteria can then invade and multiply within the bowel wall. Enteral feeding provides substrate for the bacteria. Pneumatosis intestinalis develops, and the bowel frequently ruptures. Abdominal signs include abdominal distention, tenderness, ileus, and ascites. The condition may appear as a fulminant, rapidly progressive disease or progress at a much slower pace.[94,95] One affected equine neonate was premature and was undergoing treatment for respiratory distress when the abdominal crisis occurred. Another was a term foal that had experienced a prolonged delivery and was presented at 24 hours of age because of weakness and abdominal pain. Abdominal distention and abdominal pain, followed by ventral colon rupture, were noted in both foals.[93]

314

315

Clinical signs associated with varying degrees of hypoxic, ischemic gut injury include ileus, gastric reflux, colic, lethargy, abdominal distention, and diarrhea. Reflux and feces may be positive for blood. Generalized sepsis often accompanies NEC. NEC should be distinguished from intestinal ileus secondary to other neonatal diseases, other surgical GI lesions, bacterial or viral enterocolitis, and intolerance to a milk diet. Although no single laboratory test is specific for NEC, the abdominal radiograph often reveals pneumatosis cystoides intestinalis, bowel wall edema, and an abnormal gas pattern consistent with ileus. Ultrasonography may reveal intramural gas accumulation. If intestinal perforation has occurred, pneumoperitoneum and septic peritonitis may also be noted.[93,94] Intestinal perforation is associated with a poor prognosis.

19.5.2.6

Gastrointestinal Ulceration

GDUD in the older suckling foal is covered in greater detail in Chapter 32. GI ulceration has also been associated with a number of neonatal diseases, including asphyxiation, enteritis, and septicemia.[96] The most significant form of the disease in this age group is cardiac gland disease—ulceration in the cardiac gland mucosa immediately beneath the margo plicatus. Ulceration presumably occurs in response to altered perfusion and may result in perforation and fatal peritonitis. In endoscopic surveys of neonatal foals in the United States, England, and Ireland, approximately one half of foals less than 3 months of age had evidence of gastric squamous mucosal ulceration.[97,98] The prevalence of lesions was greatest in 2- to 9-day-old foals and 30- to 59-day-old foals. In the young foals, typical lesions were golden-colored crusts in the squamous mucosa next to the margo plicatus along the greater curvature in association with diffuse ulceration and erosion and, commonly, squamous epithelial desquamation.[98] In one of these studies, foals that had a previous disorder (e.g., diarrhea, illness, transport) were more likely to have a glandular mucosal lesion than those that had not (9% vs 4%).[98]

The clinical signs of bruxism, excessive salivation, and colic that are commonly associated with GDUD in the 1- to 4-month-old foal are rarely observed in the neonatal foal. Frequently, gastric perforation is the first indication of the problem. Perforated and bleeding gastric ulcers have been diagnosed as early as 24 hours of age. There is also a high incidence of abomasal ulceration in calves, but rarely do they become symptomatic unless perforation occurs. Currently the cause and pathophysiology of the condition in the neonatal period is not known. Because of the difficulty of diagnosing the condition without specialized endoscopic equipment and the often catastrophic consequences of subsequent perforation or pyloric or duodenal stricture formation, antiulcer medications are often used prophylactically in the compromised neonatal foal. Foals at highest risk for ulcers are sick neonates that are not recumbent and foals with hypoxic gut damage, enterocolitis, and painful orthopedic conditions. Foals that are chronically recumbent frequently maintain a high pH that may a result of ileus and enterogastric reflux.[99] In normal foals the mean hourly baseline gastric pH ranged from 3.2 to 3.7. Milk intake had a dramatic but transient alkalinizing effect on pH. H_2 blockers including ranitidine and omeprazole significantly raised gastric pH. Ranitidine administered IV at 2 mg/kg or orally at 6.6 mg/kg significantly raised gastric pH.

Initial therapy includes the use of H_2 blockers (cimetidine 15 to 20 mg/kg orally [PO] q6h; ranitidine 6 to 8 mg/kg PO q8h), cytoprotective agents (sucralfate 20 mg/kg PO q6h), and a new class of drugs, proton pump inhibitors (omeprazole 4 mg/kg PO q24h). Omeprazole is highly effective and has the advantage of once-daily administration. Treatment regimens should continue for a minimum of 21 to 28 days. In acute stages some foals receive additional pain relief from over-the-counter antacid solutions (10 to 20 mL q3-4h). Some foals are in too much pain to nurse and benefit from withholding enteral feeds temporarily and maintaining them on a brief course of parenteral alimentation using a mixture of amino acids, lipids, dextrose, electrolytes, and vitamins. Currently recommended dosages for antiulcer medications are listed in Chapter 32.

19.5.2.7

Hemoperitoneum

Hemoperitoneum is a relatively uncommon cause of abdominal distention in the large animal neonate. The structures most commonly responsible for the hemorrhage are the umbilical vessels and the liver or spleen when ruptured secondary to trauma. Occasionally other structures such as a ruptured granulosa cell tumor may bleed.[100] Depending on the cause and severity of the hemorrhage, clinical signs relating to hypovolemia and

anemia may be mild or severe and may appear shortly after birth or in the older foal. Diagnosis of hemoperitoneum is based on the retrieval of free-flowing blood on peritoneal tap and the detection of free fluid in the abdomen. Ultrasound examination may be of benefit in detecting the source of the bleeding. Of critical importance, regardless of the source of the hemorrhage, is prevention of hypovolemic shock, and intensive patient monitoring and intervention are often indicated. Whole blood replacement may be necessary. If an internally bleeding animal with an unstable cardiovascular system is rushed to surgery without prior stabilization, profound shock may occur, and a poor outcome usually results.

19.6 DIARRHEA IN NEONATAL FOALS

Guy D. Lester

John E. Madigan

Diarrhea occurs commonly in foals of all ages and represents one of the most common medical conditions requiring veterinary intervention. The approach to diagnosis can be difficult, and establishment of a definitive diagnosis in a field setting is uncommon. The veterinarian must therefore consider a number of factors in order to construct a list of most likely causes. These factors include the age of the affected animal, the numbers of foals affected, the volume and character of the feces, and the duration of signs. Some limited diagnostic tests can be used to rule in or out many of the common causes of foal diarrhea.

In some foals, diarrheal diseases are associated with signs of colic. The abdominal pain can be severe and can mimic that seen in foals with strangulating intestinal lesions, making case management difficult. Colicky signs frequently precede the onset of diarrhea. Passage of a nasogastric tube is as important in colicky foals as it is in adults. Foals with intestinal ileus or inflammatory diseases of the small intestine commonly produce large volumes of gastric fluid on reflux. The control of pain is required in order to reduce the chances of injury and to facilitate evaluation. Intramuscular butorphanol can be very helpful in providing pain relief in foals with colitis. α_2-Adrenergic agonists should be used with caution in neonates because of their depressive effect on the cardiopulmonary system. If they are to be used, then start with lower doses or consider combining with butorphanol. Nonsteroidal antiinflammatory drugs should be avoided until a diagnosis is established. Neonatal foals generally tolerate flunixin well but require a slightly larger dose rate but reduced frequency when compared with older animals.[101,102]

315
316

There are many causes of diarrhea in young foals, including bacteria and bacterial toxins, viruses, nutritional factors, parasites, and antibiotic use. Normal physiologic adaptive processes can also produce diarrhea in most foals.

19.6.1 DIFFERENTIAL DIAGNOSES

19.6.1.1 Bacteria

E. coli is the most important mediator of systemic sepsis in newborn foals but is not a common primary cause of diarrhea in this age group. Some reports implicate an association between *E. coli* and diarrhea in foals. Enterotoxigenic *E. coli* was isolated from a 3-day-old diarrheic foal from Virginia.[103] The isolate was of the 0101 serotype, was heat labile-like—toxin positive, but negative for heat stabile. Earlier inoculation studies indicated that F4 (formerly K88)-positive *E. coli* was not likely to cause diarrhea in foals, although it may have a synergistic role in foals infected with other potential pathogens, such as rotavirus.[104,105]

Intestinal disease mediated by clostridial toxins occurs in foals worldwide. The toxins are most commonly derived from biotypes A and C of *Clostridium perfringens* or from *Clostridium difficile*. Classic intestinal clostridiosis of foals is caused by *C. perfringens* biotype C and is characterized by colic, rapid dehydration, cardiovascular collapse, and hemorrhagic diarrhea. The disease occurs most commonly in foals less than 10 days of age, and often less than 36 hours of age. It is associated with a high mortality, and outcomes are rarely influenced by treatment.[106] Death may occur rapidly, and occasionally it occurs before any diarrhea has been passed. Biotype C produces both alpha- and beta-toxins, along with variable amounts of enterotoxin. Cases can occur sporadically or as outbreaks and on some farms occur annually, presumably associated with carriage in specific mares. Biotype A of *C. perfringens* has become well recognized as a specific cause of foal diarrhea over the past decade. Biotype A produces alpha-toxin and enterotoxin and is associated with a slightly lower mortality rate than biotype C. Affected foals are more likely to respond to directed or supportive care.[106] The development of clinical signs is rapid, and diarrhea may or may not contain blood; in ‘our experience passage of bloody diarrhea is common but usually very transient. Reported risk factors for *C. perfringens* diarrhea in neonatal foals in Colorado include breed (stock horse type); birth on dirt, sand, or gravel; housing in stalls or on dry lots during the first 3 days of life; and maternal feeding practices. Feeding a low-grain diet prepartum was associated with a decreased risk of neonatal disease.[107] Hematologic findings are consistent with toxemia. This includes hemoconcentration; an initial leukopenia, characterized by a neutropenia with a left shift to immature forms and toxicity; and a lymphopenia. In chronic cases a rebound leukocytosis and hyperfibrinogenemia may develop. Altered coagulation may be evident clinically through prolonged bleeding or spontaneous hemorrhage or through a propensity to develop thrombosis.

A definitive diagnosis of *C. perfringens* diarrhea is rarely established in practice. The diagnosis is usually based on signalment, clinical features, and outcome, rather than on detection of specific clostridial toxins. Positive fecal culture is strongly supportive, noting that healthy foals may shed low numbers of *C. perfringens*. Identification of toxin is ideal but is limited because of availability of appropriate commercial assays. Fecal enterotoxin detection assays are available but lack sensitivity, particularly with biotype C isolates. Biotyping of *C. perfringens* isolates after culture can be achieved using polymerase chain reaction (PCR) analysis for toxin gene sequences. This may be helpful in increasing the accuracy of the diagnosis but again falls short in establishing a definitive cause. Fecal Gram stain is easy to perform and may support an early clinical suspicion of disease if there are abundant numbers of large gram-positive organisms or spores present.

Clostridium difficile can produce an identical clinical syndrome to *C. perfringens,* although it appears to be more variable with respect to fecal blood. It also occurs as sporadic cases or as clusters or outbreaks. It is important to recognize that clostridial infection can produce a severe inflammatory syndrome that is restricted to the small intestine and may not cause diarrhea. Affected foals can present with signs that mimic strangulating small bowel disease including severe abdominal pain, gastric reflux, and sanguineous peritoneal fluid. Two principal toxins can be liberated from *C. difficile*, an enterotoxin (toxin A) and a cytotoxin (toxin B). Both nontoxigenic and toxigenic strains exist and can be differentiated only after culture using molecular techniques. Consequently, commercial toxin tests (available for both toxin A and toxin B) are recommended in addition to fecal culture to establish a diagnosis. As with *C. perfringens* cases, a fecal Gram stain can also increase suspicion. Hematologic changes associated with *C. difficile* infection can mimic those associated with *C. perfringens* disease.

Most cases of clostridial enterocolitis require aggressive medical intervention, irrespective of clostridial type. Antimicrobial therapy should be both specific and broad spectrum. Targeted antimicrobial treatment typically includes both metronidazole and penicillin. The majority of affected foals require, at minimum, intravenous

crystalloid solutions; some also benefit from plasma or synthetic colloids and inotrope and vasopressor therapy. Additional therapies include *C. perfringens* biotype C and D antitoxin, di-tri-octahedral smectite clay, and lactase enzyme replacement.[108,109] The use of *C. perfringens* antitoxin and toxoid is off-label and not without some risk. Pretreatment with antihistamines before antitoxin has been suggested.[108] Prevention of clostridial enterocolitis centers on hygienic housing practices and avoidance of overfeeding of late pregnant mares. Affected foals and their mares should be isolated and strict protocols instituted to limit cross-contamination. Administration of *C. perfringens* type C and D toxoid to pregnant mares has been used with anecdotal success on farms with recurrent problems with *C. perfringens* biotype C. The use of prophylactic metronidazole is highly controversial but understandable on properties with a high disease prevalence. Some isolates of *C. difficile* are reportedly resistant to metronidazole,[108] and although this appears to be dependent on geographic location, the widespread prophylactic use could promote resistance. Prophylactic use of probiotic preparations has also been commonly recommended but is difficult to justify on the basis of limited and conflicting efficacy data.[110,111]

Bacteroides fragilis is a gram-negative anaerobic rod and occurs in both enterotoxigenic and nonenterotoxigenic forms. Enterotoxigenic strains of *B. fragilis* have been incriminated with diarrhea in several species including lambs, calves, pigs, humans, and foals.[112] Enterotoxigenic *B. fragilis* was isolated from young foals (aged 2 to 60 days) with diarrhea.[113] Half of these foals had other potential pathogens detected, including *Salmonella* or rotavirus. In a study reviewing 20 isolates of *B. fragilis* from hospitalized foals with diarrhea, only four had the enterotoxin gene.[112] The most common isolate from foal feces was a nonenterotoxigenic strain, casting doubt as to clinical relevance.

316

317

Enterococcus (group D *Streptococcus*) *durans* has also been implicated as a cause of diarrhea in several species including foals.[104] Similarly, *Aeromonas hydrophila* was isolated more commonly from foals with diarrhea than from control animals, suggesting a potential role in foal diarrhea.[114]

R. equi is an important cause of pulmonary disease in foals. Although abdominal involvement appears common, the relevance of *R. equi* as a significant primary enteric pathogen in terms of number of animals affected is likely small. An intestinal syndrome has been directly attributed to *R. equi* that involves necrosis of the small intestinal Peyer's patches and multifocal thickening and necrosis of the cecum and large intestine.[115] The changes include multiple areas of intestinal ulceration with a thin covering of fibrin and neutrophils. There is also an associated mesenteric lymphadenopathy. The diagnosis of *R. equi* ulcerative colitis is difficult for a variety of reasons. In contrast to *Salmonella* infection, in which recovery of the organism from the feces has significance, the recovery of *R. equi* is common in asymptomatic animals. Up to 100% of foals older than 2 weeks of age may shed large numbers of the bacteria ($>10^4$ colony-forming units [cfu] per gram of feces).[116]

Salmonella infection of neonatal foals is also associated with high mortality. As with clostridial infection, cases can occur sporadically or as part of an outbreak. Mares provide the most important source of *Salmonella* to newborn foals, but it is rare that both mare and foal develop clinical disease. Clinical signs can become apparent by 24 hours of age but are more common in older foals. The severity of signs is related to virulence of the serotype involved, inoculation dose, and level of host immunity. In contrast to adult infections, detectable bacteremia occurs commonly in affected foals. Consequently foals that may survive the initial intestinal or systemic disease remain at risk for secondary complications that include osteomyelitis, synovitis, meningitis, uveitis, hepatitis, or pyelonephritis. In some foals these complications may not become clinically apparent until days or weeks after resolution of enteric disease. Therefore appropriate and sustained broad-spectrum antibiotic therapy is important in foals known to be affected. The selection of antibiotic should be

based on known sensitivity patterns, understanding that in vitro sensitivity may not accurately translate into clinical efficacy because of the intracellular location of *Salmonella*. For example, the limited distribution of aminoglycosides can lead to therapeutic failure despite often promising in vitro sensitivity.

19.6.1.2

Viruses

Rotavirus is generally considered to be the most common cause of infectious diarrhea in foals. There are seven known groups of rotavirus (A through G), and many different serotypes within each group. Group A is the primary cause of rotaviral diarrhea in foals, with G3 being the most common serotype. Rotaviruses have the ability to change their surface proteins over time, and this rearrangement of gene segments takes place during co-infections with other strains. This leaves the possibility for many variations of the virus.

Transmission may be direct from animal to animal or indirect through fomites. Disease occurs after a short incubation period. Experimentally, this period may be as brief as 48 hours.[117] Rotavirus replicates within the intestine and invades the lining of the proximal small intestine, causing villous cell death and a resultant loss of absorptive area. Diarrhea may result from several mechanisms: (1) a loss of absorptive capacity coupled with a decrease in lactase production can lead to an osmotic load of undigested lactose delivered to an immature hindgut; (2) a compensatory crypt cell proliferation may cause an increase in intestinal secretion; and (3) the virus produces an enterotoxin that causes or contributes to the development of diarrhea. The putative viral enterotoxin and cytotoxin, NSP4, is a nonstructural glycoprotein of rotavirus that is released from virus-infected enterocytes.[118] NSP4 is a noncompetitive inhibitor of the Na-glucose symporter and also enhances intestinal chloride secretion.

Disease can be seen between 2 and 160 days of age but is most common in foals less than 60 days old. Indeed, most clinical infections probably occur between 5 and 35 days of age. The presence and severity of diarrhea are highly dependent on the degree of hindgut maturation. Consequently, infection in foals less than 2 weeks of age may result in life-threatening watery diarrhea, whereas infected older foals may have minimal or no diarrhea because of effective colonic compensation of osmotic and fluid loads. Diarrhea when present is often watery but is nonfetid in odor.

There is serologic evidence that broodmares may have an important role in propagation of the virus within a herd. Infections can occur as isolated cases or as outbreaks following periods of overcrowding and stress. Shedding after infection is usually complete by 10 days after the cessation of clinical signs but may occur intermittently for up to 9 months.[119] The virus can persist in the environment for up to 9 months, and disinfection usually necessitates the use of substituted phenolic compounds.

The diagnosis of rotaviral diarrhea is based on an appropriate signalment, clinical signs, and detection of the virus in feces. Tests include electron microscopy and commercial immunoassays (latex agglutination or enzyme-linked immunosorbent assay [ELISA]). Virus is shed in large concentration early on during infection.[120] Central to the management of affected foals is maintenance of hydration through enteral and/or intravenous fluid therapy. Bismuth subsalicylate is commonly administered to foals with diarrhea, irrespective of the underlying cause.

Prevention involves good hygiene and reduction in crowding. Vaccination of mares during pregnancy has yielded variable results in terms of efficacy.[121,122] Some evidence suggests that vaccination may at a minimum delay the onset of disease, thereby reducing both the severity and duration of diarrhea. Limited data from Japan indicate a potential benefit of bovine colostral immunoglobulin powder in the prevention of

rotaviral diarrhea.[123] A commercial egg-protein—derived supplement has also been used in foals to reduce the prevalence of neonatal diarrhea, but controlled research data are lacking.

Coronavirus can also cause diarrhea in foals during the neonatal period, although it appears to be very uncommon.[124–127] The few reports of clinical disease indicate that disease caused by coronavirus can be very severe. Antemortem diagnosis can be made using electron microscopy, serology, or commercial fecal-capture ELISA. As with rotaviral infection, shedding is greatest in the early stages of disease. Adenovirus is unlikely to play an important role in foal diarrhea, with the exception of foals with severe, combined immunodeficiency syndrome.[128]

19.6.1.3 Parasites

Strongyloides westeri is a common parasite of foals, with early infection of the foal occurring through mare's milk. Experimental studies have indicated that higher numbers of infective larvae than are found in milk are needed to produce diarrhea.[129] In addition, foals with high egg counts (prepatent period 8 to 14 days) are often asymptomatic. *S. westeri* is susceptible to a variety of anthelmintics, including ivermectin.[130] *Eimeria leuckarti* is commonly found in feces of foals from approximately 30 to 125 days of age.[131] It is unlikely to be a cause of diarrhea in foals.[132]

317
318

Cryptosporidium parvum is not considered to be an important pathogen of foals in terms of numbers of animals diseased. Based on epidemiologic studies the parasite appears to be concentrated in some breeding operations.[133] Foals diseased with *Cryptosporidium* shed enormous numbers of infective oocysts into the environment. The parasite is considered to be coccidian-like but differs from coccidia in terms of size (4 to 6 μm diameter compared with 23 to 34 μm for other coccidia), host specificity (not host specific), pathogenesis (invades only epithelium), and drug sensitivity (resistant to many drugs). Infection is by the fecal-oral route. The oocysts can survive in the soil or water for months. They do not require a period of sporulation outside of the host to become infective. In a study of asymptomatic foals in Ohio and Kentucky, it was reported that between 15% and 31% of foals were shedding *Cryptosporidium* and that shedding began between 4 and 19 weeks of age and persisted no more than 14 weeks.[134] All shedding had ceased by weaning and was not identified in adult horses. Each generation of the *Cryptosporidium* lifecycle is brief, with maturation occurring in as little as 12 hours. Consequently, the prepatent period is very short, approximately 72 to 96 hours. Although not determined in foals, a heavily infected calf can shed approximately 50 billion oocysts within a 7-day period.

The diagnosis is usually made through microscopic examination of the feces. Acid-fast or Ziehl-Neelsen stains are required to detect oocysts. Immunofluorescence assays and flow cytometry techniques have also been described. *C. parvum* infection may be seen with concurrent enteric or systemic infections. The disease is generally self-limiting in immunocompetent animals. Historically the pharmacologic control of *Cryptosporidium* has been difficult, but paromomycin, nitazoxanide, or azithromycin may be efficacious.

Giardia may be found in normal foals, with infection rates reported to be 17% to 35%. *Giardia* is present in all age groups, and it is believed foals acquire infection from nursing mares. Concurrent infection with *Cryptosporidium* and *Giardia* may be observed. Disease should be suspected if large numbers of parasites are seen on fecal analysis. Affected animals should respond within a few days to treatment with metronidazole; failure to respond should alert to other pathogens.

19.6.1.4

Nutrition

Nutritional causes of diarrhea include overingestion of milk (as might occur when the mare and foal are separated and rejoined) or overfeeding orphaned or sick foals. Overwhelming the ability of the small intestine to digest and absorb results in presentation of milk to the colon, where it is fermented and produces osmotically active sugars and acids.[135] In a controlled study of foals less than 5 days of age, an elemental isotonic diet (Osmolyte) produced diarrhea in healthy foals when fed as the sole source of nutrition. Older foals fed a similar diet apparently did not develop diarrhea.* Caution should be exercised in using elemental diets designed for humans in the foal without adequate prior testing of tolerance to the diet. Orphan foals and foals fed commercial mare milk replacer may experience diarrhea associated with these diets. Foals that are fed raw cow's milk frequently experience diarrhea and failure to thrive. Cow milk replacer uncommonly causes diarrhea but remains a less than ideal replacement. In contrast, foals fed goat's milk grow well and rarely develop diarrhea, although they may develop a metabolic alkalosis of minimal to no clinical significance.

Transient lactase deficiency has been proposed in foals.[137–139] An oral lactose tolerance test is conducted by a 4-hour fast and administration of 1 g/kg of body weight in a 20% solution of α-lactose powder and observation of an increase of plasma glucose of 35 mg/dL by 90 minutes.[139] It has been postulated that agents such as rotavirus that damage epithelial cells may cause prolongation of the diarrhea because of temporary lactase deficiency (lactase is produced in mucosal cells). Lactase and cellulobiase are present at birth and decline after 4 months of age.[140]

* Kohn CA: Personal communication.

19.6.1.5

Foal Heat Diarrhea

Diarrhea developing during days 5 to 14 of life has been termed *"foal heat diarrhea"* because of the time relationship to the occurrence of postfoaling estrus in the mare. Diarrhea has developed in foals in this age group that have been raised separated from the dam on a consistent diet and isolated from pathogens, so it does not appear to be causally related to estrus. There is no demonstrable change in the composition of mare's milk during this time period.[141] *S. westeri* has been investigated and is not the causative agent of foal heat diarrhea.[129] The most likely cause of foal heat diarrhea is the establishment of normal flora in the hindgut. Foal heat diarrhea is typically preceded by coprophagy 2 to 3 days before the onset of diarrhea.[142] Classic foal heat diarrheas are mild and require no specific therapy. Continued diarrhea, fever, or depression with signs of reduced sucking activity on the mare should raise concern about other causative agents and should prompt appropriate diagnostic testing and treatment.

19.6.1.5.1

Clinical Pathology and Diagnostic Imaging

In addition to the fecal tests described under specific causes, tests for signs of systemic involvement are indicated in foals with frequency and amounts of diarrhea that may produce dehydration or in foals with fever and depression and/or loss of suck reflex. CBCs may indicate toxemia or systemic sepsis with neutropenia and shifting to immature forms. Computation of a sepsis score is indicated in foals with diarrhea that are less than 7 days of age. Assessment of renal function through BUN, creatinine, and urinalysis may reveal renal azotemia of prerenal or renal origin and warrant prolonged fluid therapy.

Assessment of electrolyte and acid-base balance is warranted in neonatal diarrheas, because hyponatremia caused by losses in the GI tract and renal compromise can be significant. Prolonged diarrhea can lead to significant metabolic acidosis, requiring fluid and bicarbonate replacement (see p. 355). Fecal culture and determination of fecal leukocytes and occult blood are additional diagnostic tests that may indicate a more severe disease condition. Fecal leukocytes are common in diseases caused by enteroinvasive pathogens, such as *Salmonella*. Ultrasound and radiography are also helpful at differentiating enteritis or colitis from other causes of colic or abdominal distention.

19.6.1.5.2

Treatment and Prognosis

The three main components of therapy for diarrhea in the neonatal foal consist of (1) fluid therapy (either oral or intravenous), (2) intestinal protectants and adsorbents, and (3) antibiotics if indicated to treat suspected bacteremia or clostridiosis. Sodium-containing isotonic intravenous fluids are an important component of diarrhea therapy in the compromised neonate. Potassium is lost in severe diarrhea and, if hyperkalemia is not present, should be supplemented by adding 15 to 20 mEq/L of KCl to fluids. Foals that are not nursing normally may have hypoglycemia and may need glucose-containing fluids. Acid-base correction by volume expansion and replacement of bicarbonate can be lifesaving and blood pH and calculated bicarbonate concentrations should be monitored frequently when significant intestinal fluid losses occur.

318

319

In general terms, milk should not be withheld from foals with diarrhea. The clear exceptions are foals with colic and those with bloody diarrhea. The foal can be muzzled for 8 to 12 hours while the mare is milked out, and the foal provided oral fluids through stomach tube or a bottle if a suck reflex is present. Although labels of electrolyte replacers do not always specify “for use in foals,” many preparations used in calves (see Table 20-9) have been used successfully in foals. Most of these preparations provide insufficient energy and should be used for short intervals of no more than 24 to 36 hours unless PN of some type is provided to maintain blood glucose levels.

Intestinal protectants may be all that are required in uncomplicated cases or may be used in conjunction with other therapies. Bismuth subsalicylate, kaolin or pectin, and activated charcoal have been used for this purpose. Suggested advantages of bismuth subsalicylate[90] are its neutralization of bacterial toxins and antisecretory effect through its local antiprostaglandin activity.[143,144]

Systemic antibiotics should be used in the neonate with diarrhea that may be septicemic or may have compromised immunity. Blood cultures (see Chapter 18) should be obtained before initiation of antimicrobial therapy. Antibiotics with a spectrum against gram-negative and gram-positive organisms should be used. In general terms, renal toxicity associated with aminoglycoside use is uncommon in clinical practice. The clear exception are foals that are dehydrated, most commonly because of ongoing losses through diarrhea. Consequently the monitoring of renal function is indicated when potentially nephrotoxic drugs are used.

Plasma therapy for hypoproteinemia associated with FPT or protein-losing enteropathy is useful to maintain plasma oncotic pressure and expected protein binding of medications. Diarrheic foals with albumin levels below 2 g/dL or total plasma protein levels less than 4.2 g/dL may benefit from plasma therapy.

19.6.1.5.3 Prevention and Control

Prevention is best accomplished by minimizing density of populations of horses, separating of age groups, providing appropriate sanitation and hygiene (see Chapter 46), and obtaining adequate colostrum of good quality (see Chapter 53).

19.7 LAMENESS AND RELUCTANCE TO WALK

John E. Madigan

Guy D. Lester

19.7.1 INFECTIOUS LAMENESS

19.7.1.1 Etiology

Septic arthritis, septic physitis, and osteomyelitis as a complication of or sequel to bacteremia produce lameness and reluctance to move. Terminology to describe this condition has included “joint-ill,” “navel-ill,” septic physitis, septic polyarthritis, and septic epiphysitis.[145] Blood-borne bacteria from a previous illness or concurrent with an active nidus of infection produce infection in synovial membranes, growth plates, or periarticular bone. Sources of infection include primary bacteremia with or without FPT[146] (see Chapter 53), pneumonia, umbilical infection, enteritis, and extension of local infection from penetrating wounds. Thirty eight of 140 foals with confirmed septic arthritis demonstrated evidence of umbilical disease. In foals, bacteria that produce septic arthritis include the causative agents of systemic sepsis: *E. coli, Klebsiella* species, *Actinobacillus equuli, Salmonella* species, *R. equi,* and *Streptococcus* species.[146] A review of 78 foals with septic arthritis ranked the frequency of isolation of bacterial agents. Gram-negative bacteria were cultured from 51 of 78 foals. In addition, the probability of susceptibility of these isolates to various antibiotics was determined. Blood culture produced more bacterial isolates, although joint aspiration yielded bacteria in 69% of foals sampled.[147] Bacterial species cultured from blood and synovial fluid were identical in 16 of 88 foals. Negative cultures occurred in 31% of foals with later confirmed septic arthritis.[147] Gram-negative bacteria were more common in younger foals, and gram-positive infections became increasingly more common with advancing age of the foal.[147]

19.7.1.2 Clinical Signs and Differential Diagnoses

Signs may be extremely variable. Sudden onset of lameness in one leg in an apparently healthy neonate with or without joint distention, pain, or edema may be noted. Other presentations may be observed, consisting of sudden onset of lameness with systemic signs of illness or evidence of multiple joint distention, pain, and edema in a neonate with obvious illness and a diagnosis of septicemia. Prematurity or FPT should raise the index of suspicion. The chief differential diagnosis is trauma; lameness is often attributed by the owner to the dam's stepping on the newborn. Any neonate less than 45 days of age with sudden onset of lameness should be considered infected until proven otherwise.

19.7.1.3

Clinical Pathology and Radiology

Diagnosis may be obvious, with signs of septicemia, a positive sepsis score, and a swollen, hot, and painful joint. Peripheral leukocyte counts, rectal temperature, level of alertness, and appetite may be normal with localized infections. Joint aspiration may reveal normal synovial fluid if the infection is in the early stages of synovial membrane inflammation or physeal or bone involvement.[145] Synovial fluid with greater than 10,000 WBCs/μL and greater than 70% neutrophils indicates that infection is likely.[146] Cytology and Gram stain of the synovial fluid may further aid diagnosis. Thin, turbid, or brown synovial fluid with increased leukocytes is considered evidence of infection.[145] Culture of synovial fluid is often negative, even when infection is present. Improved recovery of bacteria may be obtained with thioglycolate broth or brain-heart broth with an agar slant and sodium polyanethole sulfonate (SPS) to prevent clotting and inhibit aminoglycoside and trimethoprim antibiotics.[148] Normal synovial fluid does not rule out septic physitis or osteomyelitis.[145] Careful examination of high-quality radiographs is important for the detection of bone lysis in cases of osseous infection. Initial radiographs may be normal because the degree of damage is often not detectable for 10 to 14 days after initial infection occurs.[145] Radiographic features of septic arthritis include soft-tissue swelling, widening or collapse of the joint space, osteoporosis, and osteosclerosis. Repeat radiographs taken at 3- to 7-day intervals are valuable for assessing the degree of damage if lameness persists.[145] Ultrasound may be used to confirm involvement of the joint and rule out periarticular or tenosynovial infection to avoid iatrogenic contamination of the joint during arthrocentesis. Joint distention and hyperechogenic fragments in the synovial fluid are suggestive of septic arthritis. Normal synovial fluid is anechoic. Bone scans or CT may facilitate early detection.

319
320

19.7.1.4

Pathophysiology

Hematogenous spread of bacteria resulting in bone infection may follow a variety of pathways.[145] A nidus of infection may develop at the junction of cartilage and subchondral bone. The low pressure, slow flow, and reduced oxygen pressure of the blood supply at cartilage-bone junctions may predispose to establishment of infection in these areas. Level of immunity and degree of maturation of bone of the foal may be additional predisposing factors.[145] Destruction of the epiphysis and extension of infection into the joint may be primary in some cases, rather than starting as a primary synovial membrane infection that spreads to the epiphysis and physis. A classification has been proposed to reflect the various pathogeneses of infection (see Box 19-2). Infection of the small bones of the tarsus has been reported to be more common than that of the carpus,[149] and the metaphysis of ribs and vertebral bodies may be involved.[146] Synovitis produces severe inflammation and depletion of the cartilage matrix and collagen framework, which can cause irreversible damage.[145,146] Eburnation of cartilage leads to exposure of subchondral bone and extension of infection in bone.[145]

19.7.1.5 Treatment

Aims of treatment are to remove the infectious agent, protect and minimize cartilage damage, and minimize secondary osteoarthrosis. If partial or complete FPT has occurred, an additional aim is to provide immunoglobulins through plasma transfusion (volume dependent on IgG concentration, but 2 or more liters IV may be required).[145] Treatment described for bacteremia should be used promptly. Umbilical ultrasound should be performed, because many infections may be not be visible externally. Systemic antibiotics provide adequate levels of antibiotic in normal and inflamed joints.[145,150] Antibiotics or antibiotic combinations with both gram-negative and gram-positive spectrum should be used initially, with selection modified by culture results. Ampicillin or a first-generation cephalosporin in conjunction with amikacin or gentamicin has had a good probability of antimicrobial sensitivity.[147] The third-generation cephalosporin ceftiofur may be used as monotherapy. Antimicrobials (antibiotics) should be continued for at least 3 weeks. Joint lavage with 1 to 3 L of balanced polyionic buffered (pH-adjusted) fluids helps to remove bacteria and inflammatory mediators that damage cartilage and improves outcome.[147] An infected joint is a medical emergency, and treatment should be carried out immediately after clinical diagnosis of probable sepsis, even before all cultures and clinical pathology test results are back. Arthrotomy or arthroscopic lavage for joints with fibrin and debris has been advocated and appears effective.[148,151] Delivery of antibiotics to chronically infected tissues via regional limb perfusion or intraosseous infusion has been described.[152] Confinement and limb immobilization may decrease pain, inflammation, and cartilage damage. Short-term use of nonsteroidal antiinflammatory drugs such as flunixin or phenylbutazone at prescribed dosages may be indicated, although the risk that these agents will induce gastric ulceration in foals is well described.

19.7.1.6 Prognosis

Duration, extent of bone involvement, and degree of damage affect the prognosis. A recent study determined that 79% of foals with septic arthritis had IgG levels less than 8 g/L (800 mg/dL). Infection of multiple joints, delay in onset of treatment, and presence of concurrent bony lesions on radiographs were associated with a poorer prognosis.[147] In one study, 67% of foals with septic arthritis were discharged when treatment was initiated within 24 hours of the onset of clinical signs.[147] Better outcomes were observed when treatment included joint lavage. Of foals treated for septic arthritis, 26% went on to perform their intended function.

If FPT has occurred and multiple joints are involved, the prognosis is poor because, in foals with FPT and lameness, multiorgan involvement is common.[146] Initial detection should warrant a guarded prognosis. The long duration of treatment and sometimes costly multiple therapeutic modalities should be discussed with the owner at the outset. Reevaluation of the patient at regular intervals is indicated. Recurrence after cessation of therapy sometimes occurs.

19.7.2 NONINFECTIOUS LAMENESS

Rhabdomyolysis in foals deficient in vitamin E and selenium may be precipitated by stress such as septicemia. Affected foals are reluctant to move, paretic, and occasionally dysphagic. Pelvic limb muscles are often palpably firm. Elevated serum creatinine kinase and electrolyte disturbances of hyponatremia and hyperkalemia may be observed.[153]

In foals, rupture of the common digital extensor tendon may be present at birth or may develop within a few days of life. Rupture occurs within the carpal synovial sheath and produces swelling over the dorsolateral surface of the carpus at the level of the intercarpal and carpometacarpal joints. Palpation of the fibers reveals tearing of the tendon. Splinting of the limb for 3 to 4 weeks usually results in healing.[154] 320 321

Contracture of joints or tendons of the limbs produces difficulty in movement and predisposes to FPT by impeding the ability to adequately nurse. Degree of contracture varies from mild to severe and may be associated with scoliosis and/or torticollis.[155] Foals with congenital contracture of tendons of the front limbs may spontaneously rupture the common digital extensor tendon. Conservative therapy consisting of splinting the front limbs to induce tendon laxity may be helpful.

19.7.2.1 Developmental Causes

Incomplete ossification of the cuboidal bones (see Fig. 19-1) of the carpus and tarsus of newborn foals is considered to be related to the development of flexural and angular deformities of the foal.[156] Twins, premature foals, foals that are small for gestational age, and foals with in utero acquired infection are likely to have incomplete ossification of cuboidal bones at birth.[156,157] Radiographic analysis and grading of the degree of ossification have been suggested for these foals.[157] Foals with substantially reduced ossification may damage bone with limb loading. Limited exercise may be prudent until ossification begins to increase radiographically, which can be within 7 days. Hypothyroidism (see Chapter 41) has been identified in foals with angular limb deformities, contracted tendons, and tarsal bone collapse.[158,159]

19.8 PATENT URACHUS, OMPHALITIS, AND OTHER UMBILICAL ABNORMALITIES

John E. Madigan

19.8.1 PATENT URACHUS

Patent urachus is a persistence after birth of the tubular connection between the bladder and umbilicus. The urachus drains the bladder into the allantoic sac during gestation. Urine flow should gradually change, with some urine entering the amniotic sac through the urethra in later gestation. At birth, with umbilical cord rupture the urachus should be closed, and urine should be voided through the urethra. Foals with a patent urachus may dribble urine from the urachus during or after urination or may simply have a constantly wet umbilical stump.

19.8.1.1 Etiology

Various causes have been suggested for failure of the urachus to close and completely involute. Early severance or ligation of the umbilical cord, inflammation, infection, and excessive physical handling of the neonate have been implicated.[160] Rather than being the original cause for hospital admission, patent urachus develops as a complication of hospitalization in a significant percentage of foals in neonatal intensive care. Weakness of abdominal musculature may contribute to the problem in sick foals.

19.8.1.2 Clinical Signs and Differential Diagnosis

Differential diagnoses include concurrent infection of the navel (omphalophlebitis). Ultrasound may assist the diagnosis and determine the involvement of umbilical arteries or vein.[161] Moist hairs around the umbilicus and visualization of fluid coming from the navel are diagnostic. Ultrasound examination of the internal structures of the umbilicus is strongly recommended.

19.8.1.3 Clinical Pathology

Identification of concurrent infection is essential. A complete physical examination should be performed. If abnormalities are noted, serum IgG, CBC, and urinalysis are helpful for detecting susceptibility to infection and presence of systemic or urinary tract infection.

19.8.1.4 Pathophysiology

Congenital patent urachus caused by excessive torsion on the umbilical cord in utero occurs in 6% of normal foals.[162] The obstruction of the urachus caused by the torsion causes retention of urine in the bladder and overdistends the proximal urachus, which interferes with normal involution.[162] Infection of umbilical structures or the urachus itself may result in inflammation and failure to completely involute. In a review of 16 cases of umbilical cord infections in foals, 13 of the foals had patent urachus.[163] The majority of these foals had acquired patent urachus after birth, with the youngest age of onset being 3 days and the mean age of onset being 12 days. Excessive manipulation and improper lifting of the foal's abdomen in the presence of high urethral sphincter tone may force urine within the bladder out into the involuting urachus. In our experience, farms have experienced outbreaks of patent urachus when procedures (such as tests for FPT) have been

implemented that require handling of foals in the first 12 to 24 hours of life. A similar cause may be responsible for the increased incidence of patent urachus in hand-reared calves.

19.8.1.5 Treatment and Prognosis

Therapy consists of either conservative management through monitoring or medical treatment for infection and cauterization of the urachus with iodine, phenol, or silver nitrate sticks applied into the urachus. Persistence of urine dribbling despite cauterization, the detection of involvement of other umbilical structures through ultrasound, and a rent in the urachus that produces subcutaneous swelling are indications for surgery. Not all foals that have persistent patent urachus have an infected umbilicus. Use of general anesthesia and removal of the entire urachus to the tip of the bladder are performed in foals with an infected or enlarged urachus. Associated arteries and veins should be ligated and removed if they are infected or necrotic. Merely ligating the exterior stump can trap organisms and cause infection. In our neonatal unit the majority of patients with acquired patent urachus respond to conservative therapy. Late-onset patent urachus (5 days of age) may be more refractory to conservative therapy.[163] Complications are uncommon but may include bladder necrosis and uroperitoneum caused by extension of infection and inflammation of the urachus.

19.8.1.6 Prevention

Allowing the umbilical cord to rupture without ligation or the careful use of specific umbilical clamps after birth has been suggested to decrease the incidence of patent urachus. Minimum handling of neonates and careful restraint may prevent pressure buildup in the bladder and subsequent patent urachus.

19.8.2 OMPHALITIS AND OMPHALOPHLEBITIS

19.8.2.1 Definition and Etiology

Omphalitis is inflammation of umbilical structures that may include the umbilical arteries, umbilical vein, urachus, or tissues immediately surrounding the umbilicus. The umbilicus consists of three types of structures and undergoes functional and anatomic changes at birth. Two umbilical arteries connect internal iliac arteries to the placenta. These later regress and become the round ligaments of the bladder. One umbilical vein connecting the placenta to the liver and porta cava regresses to become the round ligament of the liver within the falciform ligament. The urachus connects the fetal bladder to the allantoic cavity. 321 322

Umbilical abscess or infection of any of the three components of the umbilicus may produce local infection or be a source of septicemia. The source of infection is most commonly the external environment, coupled with FPT. Omphalophlebitis may extend the length of the umbilical vein into the liver and result in liver abscessation.

19.8.2.2 Clinical Signs and Differential Diagnosis

When the umbilicus is enlarged and draining purulent material, infection is easily noted. In other cases the umbilicus may be dry and larger in diameter than expected. In addition, neonates may have a completely normal-appearing, dry external navel and be severely ill from infection of the urachus, umbilical arteries, or vein. In a neonate with sepsis without external signs of infection, involvement of the umbilicus can be difficult to determine. The presence of pain on palpation of the umbilicus indicates inflammation. Ultrasound aids in

the detection of involvement of the urachus or arteries and vein.[161] The umbilical area of neonates less than 20 days of age with fever of unknown origin should be scanned. Hematoma developing after umbilical rupture may produce distention of the umbilical stump shortly after birth.

Overt signs of infection include heat, swelling, purulent discharge, or pain. Concurrent signs of systemic infection such as joint infection, pneumonia, diarrhea, meningitis, or uveitis may be noted. Infection in more than one umbilical vessel in the neonate is common, and urachal involvement is frequent. Umbilical abscessation that is walled off and does not involve deeper structures is a less severe problem and may be treated with drainage without surgical removal of the entire umbilicus. The depth of involvement may be determined by standing behind the neonate and pressing the hands together above the umbilicus to detect internal masses and painful areas.

19.8.2.3

Diagnostic Methods

In addition to detection of overt umbilical inflammation as described, ultrasonography may aid in evaluating a normal-appearing navel.[164] The umbilical vein, arteries, and urachus may be imaged in the newborn (see Chapter 18). The umbilical arteries leave the umbilical stalk and course on the outer edges of the urachus in a parallel fashion.[164] In the foal the urachus connects the apex of the bladder with the umbilicus and is located along the midline immediately adjacent to the body wall. Persistent dilation of the umbilical vein or arteries with a hypoechoic-to-echogenic fluid is seen with infection. If ultrasound is performed by a skilled ultrasonographer familiar with normal ultrasonographic findings of the umbilicus, there is an excellent correlation between surgical and ultrasound findings.[164]

19.8.2.4

Treatment and Prognosis

Early treatment with antibiotics and supportive care as described for the septicemic foal (see Chapter 18) may allow resolution before development of abscessation and distention of the urachus or the umbilical arteries and vein. Established infection, which may occur within 24 hours, may necessitate surgical removal of involved structures in addition to medical therapy.[163] When omphalophlebitis extends into the liver, the umbilical vein may be marsupialized to facilitate drainage and flushing. The prognosis is very good when adequate passive transfer of colostral immunoglobulins has occurred and when joints or other structures are not involved. Sequelae such as renal abscessation, joint or bone infection, peritonitis, and other complications described for septicemia may develop if therapy is started too late or discontinued prematurely.

19.8.3

ANEMIA AND ICTERUS

John E. Madigan

19.8.3.1

Definition and Etiology

Anemia in the neonate should be interpreted in the context of the realization that normal hematologic values of the neonate may vary from those of the adult. In foals, values of hemoglobin and PCV are similar to those in adult horses but decrease during the first weeks and months of life to below those in adults.[165] Foals have low iron stores during the first 5 months of life; this is reflected in decreased serum ferritin concentration, increased serum total iron binding capacity, and decreasing mean corpuscular hemoglobin concentration.[166]

Microcyte production is observed rapidly after birth.[166] Absolute RBC and total blood volume decrease at between 2 days and 2 weeks of age and then progressively increase.[167]

In addition to frank blood loss from an injury, diseases causing anemia in the neonate include NI, non-NI immune-mediated hemolytic anemia, blood loss caused by gastric ulcer or ovarian cyst rupture producing hemoperitoneum, anemia of chronic disease associated with localized infections, piroplasmosis, and equine infectious anemia.

19.8.3.2 Clinical Signs and Differential Diagnosis

Rapidly developing anemias such as those associated with NI produce signs of weakness, pale or jaundiced mucous membranes, fever, and depression. Hemoperitoneum produces weakness and pale mucous membranes. Suspected drug-induced, immune-mediated hemolytic anemia and thrombocytopenia have been reported in the foal.[168] Intestinal parasitism does not normally lead to anemia during the neonatal period. Chronic localized infection may produce anemia of chronic disease.

19.8.3.3 Clinical Pathology

Intravascular hemolysis may produce hemoglobinuria and hemoglobinemia. Icterus develops when the ability of the liver to conjugate bilirubin is exceeded. Mainly, indirect bilirubin is elevated. Anisocytosis is observed in responsive anemias. Nonspecific stimulation of bone marrow may produce a leukocytosis.

19.8.3.4 Therapy

Determination of the nature of the anemia may allow specific treatment. NI is discussed in Chapter 53. Drug-induced or autoimmune anemias may be treated with corticosteroids (0.05 to 0.1 mg of dexamethasone per kilogram twice a day IM or IV). Blood transfusion after cross-match may be indicated when anemia develops rapidly or PCV drops below 14%. Massive red cell destruction may trigger disseminated intravascular coagulation, and the actual cause of death may be a result of activation of the clotting system by RBC destruction and reticuloendothelial system removal.[169] Associated conditions such as metabolic acidosis and hypoglycemia should be corrected. Anemia of chronic disease requires correction of the primary disease condition.

19.8.4 FEVER

John E. Madigan

19.8.4.1 Definition and Etiology

Fever (rectal temperature >38.9° C [102° F]) as a clinical sign must be interpreted differently in neonates than in the adult because of the variations of anticipated response to systemic illness, temperature regulation control differences, and susceptibility to environmental changes in temperature. In foals with septicemia, fever (> 38.9° C [102° F]) was present in fewer than 30% of cases, and hypothermia was noted in approximately 20%.[56] Consequently fever is considered an unreliable clinical sign for determination of sepsis in neonates. Older foals with localized infection such as in joints or bone are more likely to have fever.

322

323

19.8.4.2 Differential Diagnosis

The chief differential diagnoses for fever in neonates are fever caused by infections with viral or bacterial pathogens, seizures with subsequent generation of heat by muscular overactivity, pyrogens generated from hemolysis in NI, and environmentally induced hyperthermia. The condition of transient tachypnea of the newborn may produce significantly elevated temperatures in warm environments.[170] Neonatal foals have a rapid respiratory rate that appears to be an attempt at heat loss through a panting type of mechanism. Extreme care must be used in attributing the pyrexia and fever to transient tachypnea syndrome alone by ruling out the presence of infection through physical examination, chest radiographs, blood gases, and computation of a sepsis score. Pathophysiology is similar to that in the adult and is discussed thoroughly in Chapter 4.

19.8.4.3 Treatment and Prognosis

Although a conservative approach to fever in older animals may be appropriate, the presence of a fever in a neonate warrants rigorous diagnostic evaluation and aggressive therapeutic intervention. The immaturity of the neonatal immune system, the high fatality rate, and the frequency of devastating sequelae to bacterial infection warrant a complete examination of the neonate.

Because fever may be beneficial to the animal, the need to administer antipyretics to the febrile neonate is controversial. Body temperatures lower than 40.8° C (105.4° F) are not considered detrimental unless they are associated with heat stroke or seizures,[171] in which case cooling and antipyretics are indicated. Because many antipyretics are antiprostaglandins that can cause deleterious GI and renal effects, these agents should be used judiciously. Dipyrone is often used in neonates in our clinic for antipyretic response because it lacks most of the adverse GI side effects found with most nonsteroidal antiinflammatory drugs. Correction of the initiating cause and maintenance of fluid balance are also important. Prognosis depends on immunoglobulin status and stage of disease when treatment is initiated. Significant fatality rates occur in neonates with bacterial infections. Transient tachypnea has an excellent prognosis, with neonates becoming normothermic within 2 to 3 weeks of age. Clipping a long and thick haircoat, using fans in stalls, and removing the animal from direct sunlight may reduce heat stress to the neonate.

19.8.5 CYANOSIS

John E. Madigan

19.8.5.1 Definition and Etiology

Cyanosis is the purple-blue coloration observed on mucous membranes or skin caused by reduced or poorly oxygenated hemoglobin in blood.[172] Causes for this condition include congenital heart disease, respiratory impairment, or any circulatory condition that produces a right-to-left shunt. The degree of cyanosis depends on the arterial oxygen saturation, hemoglobin concentration, pH, peripheral circulation, and temperature of the neonate.[172] Shock and hypothermia are important causes of peripheral cyanosis (see Box 20-4).

19.8.5.2 Pathophysiology

The affinity of hemoglobin for oxygen is reflected in the standard oxyhemoglobin dissociation curve. This curve is similar for neonates but is affected by the amount of 2,3-diphosphoglycerate (DPG) in the erythrocyte. The foal does not have a fetal hemoglobin but has decreased amounts of 2,3-DPG, which causes oxygen to bind more tightly to hemoglobin and thus to be released in lesser amounts to the tissues.[173] Severe hypothermia and acidosis cause the oxygen dissociation curve to shift to the right and therefore contribute to tissue hypoxia. Cyanosis can be either central or peripheral.[172] Peripheral cyanosis results from increased peripheral extraction of oxygen from normally saturated blood or a significant decrease in the perfusion to an extremity.[172] In the neonate, causes include septic shock and severe hypothermia. Central cyanosis is more common in neonates and is related to congenital heart disease that causes right-to-left shunting or severe respiratory conditions that result in hypoxia. Paroxysmal atrial fibrillation in three foals with cyanosis shortly after birth is described.[174]

19.8.5.3 Treatment

Examination and clinical pathologic evaluation for metabolic causes of cyanosis, hypothermia, and cardiac abnormalities should be conducted. History, medication use, auscultation, thoracic radiographs, and arterial blood gases are useful in determining the degree of the respiratory component of cyanosis. Therapy for respiratory causes is discussed in the sections on respiratory distress. Electrocardiography and echocardiography may be required for identification of cardiac anomalies. Circulatory compromise caused by hypothermia, hypoglycemia, and shock requires aggressive fluid therapy, respiratory support, and environmental temperature correction.

19.8.6 OLIGURIA AND STRANGURIA

John E. Madigan

19.8.6.1 Definition and Etiology

In the neonate, urination is usually observed within 6 to 10 hours after birth. Frequency of voiding is every few hours. Urine volume produced in the foal is approximately 148 mL/kg/day.[175] Urine specific gravity is low (1.001 to 1.012) because of the high water content of milk. Specific gravity readings of 1.018 to 1.025 are approaching maximum in concentrated urine.[176]

The major causes of slow or painful discharge of urine (stranguria) in neonatal foals are ruptured bladder, bacterial cystitis, urachitis, and reduced urine production (oliguria) resulting from reduced renal perfusion. Pollakiuria, dysuria, and cystitis are complications occasionally observed with urachal abscesses.[176]

19.8.6.2 Pathophysiology

Ruptured bladder (see also Chapter 34) occurs most frequently in male foals and is believed to be caused by occlusion of the male urethra during birth, a full bladder, and great pressures during birth when the mare pushes to expel the fetus. Inadequate pressure flow to the kidney producing oliguria may be caused by

congenital cardiac anomalies, asphyxia, sepsis, diarrhea, or endotoxemia. Straining from cystitis can be severe and can mimic meconium impaction. Infection of the bladder may be associated with urachal infection. Inappropriate antidiuretic hormone (ADH) secretion occurs in stressed human infants, resulting in decreased urine production and electrolyte abnormalities. During periods of reduced glomerular filtration rate (GFR), drugs excreted by the kidney may accumulate, resulting in toxicity. Inability to excrete a water load associated with excessive fluid therapy may result in fluid accumulation and pulmonary or generalized edema. Uroperitoneum may result in stranguria or oliguria. Postrenal obstruction syndromes are rare in the neonate. 323
Ectopic ulcers have been reported in foals[177] as a cause of incontinence and hydronephrosis. A syndrome of 324
apparent pain on attempting the first urination is observed in some male foals; urinary bladder catheterization for 1 to 3 days may resolve the problem.

19.8.6.3

Clinical Signs

A carefully obtained history of events of the birth and neonatal period is important. Observation of defecation, posture during urination, frequency, and estimated amounts of urination should be noted. Excessive stretching of the front legs, dorsoventral flexion of the back, and colic may be observed with uroperitoneum. Detection of oliguria requires careful observation or catheterization of the bladder to determine presence of urine and amount of urine production. Free catch of urine and examination for WBCs aid in diagnosis of cystitis.

Azotemic neonates with oliguria have signs of depression, dehydration, poor pulse quality, prolonged capillary refill, reduced jugular distensibility, and retracted eyeballs. Elevated levels of serum urea and creatinine may be observed with uroperitoneum, often with concurrent electrolyte abnormalities of hyponatremia, hyperkalemia, and hypochloremia. If the presence of uroperitoneum is suspected, abdominocentesis should be performed. The fluid can be analyzed for potassium and creatinine and compared with serum values. Urea rapidly equilibrates between abdominal fluid and serum. Peritoneal fluid creatinine levels will be 1.8 to 2 times those of serum with uroperitoneum. A syndrome of high creatinine in newborn foals associated with maternal conditions or events of birth and without renal disease has been reported. Serial creatinine determinations reveal a gradual decline toward normal values over several days. Consequently a single serum creatinine determination should not be used to determine prerenal, renal, or postrenal uremia in the foal.

19.8.6.4

Treatment

Administration of balanced electrolyte solutions such as lactated Ringer's solution or saline and determination of urine production are important. Specific electrolyte and acid-base disturbances should be corrected slowly. Prolonged ischemia of the kidneys may result in permanent renal parenchymal damage. Lack of urine production after restoration of fluid balance should be an indication for diuretic therapy with furosemide (0.5 to 2 mg/kg IV) or osmotic diuresis with mannitol (0.25 to 0.5 mg/kg IV over 20 minutes and repeated in 4 hours if no response occurs). If adequate urine production has not developed, administration of dobutamine (2 to 10 g/kg/min) or dopamine (2 to 5 μg/kg/min) may be attempted. Treatment of concurrent sepsis, endotoxemia, hypoproteinemia, respiratory distress, or other abnormality should be attempted. If adequate urine flow is not produced, maintenance levels of fluids should be administered to prevent fluid overload. Body weight determinations three to four times a day help to prevent overhydration by detecting fluid accumulation. Urinalysis and clearance calculations may add further insight to the origin and degree of primary renal involvement. Progressive development of uremia and generalized edema is associated with a poor prognosis. When oliguria is present, serial BUN and creatinine determinations should be performed and urine production monitored. Recumbent neonates may be catheterized and urine production quantitated.

19.8.7 HEART MURMUR

John E. Madigan

19.8.7.1 Definition and Etiology

Heart murmurs in the neonate may be heard normally before physiologic closing of the ductus arteriosus during the first 1 to 5 days of life. Other causes of murmurs include congenital anomalies, severe anemia, and infectious valvular disease.

19.8.7.2 Clinical Signs and Differential Diagnosis

Physical examination for other signs of heart disease helps determine the severity of the murmur. Jugular pulse, weak or irregular arterial pulse, and palpable thrill indicate a serious condition. Signs of weakness, cyanosis, and tachypnea are indications of poor cardiac performance. Timing and location of the heart murmur should be determined. The electrocardiogram (ECG) may reveal atrial or ventricular enlargement. Thoracic radiography may aid in determining heart size and in detecting pulmonary edema or distended pulmonary vessels. Echocardiography may reveal atrial or ventricular enlargement, thickened ventricular walls, anomalous orientations of outflow tracts, or ventricular septal defects (VSDs).[178]

Patent ductus arteriosus (PDA) produces a continuous murmur localized over the left heart base.[179] The diastolic component may not be heard with auscultation over other parts of the heart. As pulmonary hypertension develops, the murmur is shortened to a holosystolic type with normal arterial pulse. Large shunting of blood produces a bounding arterial pulse caused by wide fluctuations of systolic and diastolic pressures.[179] The ECG is normal unless atrial enlargement is present and increasing QRS amplitudes are observed.[178] Radiographs may reveal an enlarged heart with increased vascularity caused by left-to-right shunting of blood. Echocardiography may reveal an increased left atrial and left ventricular diastolic dimension or volume and hyperdynamic septal and left ventricular wall systolic motion (depending on the degree of right-to-left shunt).[178] Catheterization and angiography may further delineate the degree of shunting.[180] Recent studies have indicated the ductus architecture changes days before birth, which prepares the ductus for closure. Triggering factors for closure include increased blood oxygenation and lower pressures resulting from vasodilation of pulmonary vasculature at birth.

VSD produces a large, harsh, holosystolic murmur that is loudest on the right cranial region of the thorax and is softer over the left heart base.[181] The ECG may be normal or may show increased amplitude of the QRS, with larger shunts and alterations in chamber size. Radiography may reveal heart size increase, left atrial enlargement, and dilated pulmonary vasculature.[178] Two-dimensional echocardiography may show aortic and septal discontinuity.[178] Injection of saline bubbles into the left ventricle and observation of bubbles in the right atrium or ventricle document a left-to-right shunting of blood.[178] Tetralogy of Fallot or other types of complex malformations often produce loud murmurs and are associated with cyanosis, weakness, fatigue, and stunted growth.[182] Tetralogy of Fallot produces a systolic ejection murmur heard at the left heart base.[178] Electrocardiography may reveal negative QRS complexes in leads I, II, and aVF, suggesting right ventricular hypertrophy.[178] Echocardiography may reveal a thickened right ventricular wall, septal echo dropout in the area of the VSD, rightward displacement of the aortic root, and an abnormal pulmonary outflow region.[178]

Saline injection into the jugular vein demonstrates right-to-left flow from the right ventricle to the left ventricle or the aorta.

19.8.7.3 Treatment

PDA has been treated by chemical closure using indomethacin in human neonates, but it has not been used in veterinary medicine.[183] Other global antiprostaglandins, including flunixin meglumine, have been used in attempts to assist with chemical closure of the ductus arteriosus in foals. The efficacy of this procedure has not been determined. Minimal fluid administration is also suggested to be of assistance. VSDs may pose few problems if the degree of shunting is small. Other complex cardiac anomalies producing murmurs may be treated symptomatically for a short time, but the long-term prognosis is extremely poor.

324 325

19.9 SUPPORTIVE CARE OF THE ABNORMAL NEONATE

Wendy E. Vaala

The vulnerability of neonates to contagious and opportunistic pathogens is amplified by adverse environmental conditions. Maintenance of a “friendly” environment is a crucial component of neonatal medicine. Any condition that prevents them from standing and nursing within 3 hours of delivery represents a potentially fatal condition. Forced recumbency alone interferes with pulmonary function; contributes to dependent lung atelectasis and increases the risk of pneumonia; compromises GI function and predisposes to constipation; increases the risk of aspiration after milk meals; exacerbates preexisting musculoskeletal weakness and favors tendon contracture; delays absorption of colostral antibodies and calories, which increases the risk of infection and hypoglycemia; predisposes to decubital sores; and contributes to poor hygiene, urachal patency, and omphalitis. Supportive care is aimed at protecting the patient from self-inflicted injury, maintaining fluid, electrolyte, and metabolic homeostasis, providing adequate caloric intake, and preventing nosocomial infections.

If recumbent, foals should be kept on soft, absorbent bedding (mattress covered in synthetic fleece, straw on top of a deep bed of shavings or rubber mats) and turned and assisted to stand every 2 hours. If the foal is thrashing, it should be manually restrained to prevent self-trauma. Padded walls and strategic placement of pillows help protect the recumbent patient. Using a temporary barrier between the mare and recumbent foal facilitates treatment of the foal yet keeps the dam within sight, sound, touch, and smell of her foal, which fosters good bonding. The foal's eyes are prone to injury with the development of entropion, corneal edema, and ulceration. To prevent these injuries artificial tears or another sterile ocular lubricant should be applied topically every few hours. If entropion develops it should be corrected promptly using one or two vertical mattress sutures. A small bleb of procaine penicillin injected into the lower eyelid provides temporary improvement for mild cases of entropion.

If the animal's body temperature is less than 100° F (37° C), efforts should be made to warm it by raising the environmental temperature, using radiant heat lamps, applying blankets, and using heating pads judiciously. An effective heat pack can be made by placing a wet towel inside two rectal sleeves and microwaving to the desired temperature. The hot pack remains dry and can be nestled alongside the foal's abdomen. If the animal is wet, it should be dried off to reduce convective heat loss. Volume expansion to restore normal cardiovascular function, peripheral circulation, and systemic BP is an essential part of the warming process. Rewarming the periphery only with external heat without simultaneously warming the core can produce peripheral vasodilation with cardiovascular collapse. The thermoneutral zone for a term foal is 23° to 25° C (73° F to 77° F).[185]

Generalized seizure activity should be controlled as soon as possible. Diazepam at 5 to 20 mg IV, given slowly to effect to a 45-kg foal, is an appropriate first choice. If seizures are severe or recurrent, then phenobarbital should be administered (3 to 10 mg/kg IV slowly over 5 to 10 minutes). Multiple doses of diazepam can cause respiratory depression and should be avoided.

Respiratory rate, effort of breathing, mucous membrane color, heart rate, and fluid balance are quickly assessed to establish the need for immediate intervention and stabilization. Depending on the type and severity of the animal's condition, postural drainage, suction, oxygen therapy, or PPV may be indicated. If shock, severe dehydration, or metabolic derangements, such as hypoglycemia, are present, fluid therapy should be initiated as soon as an intravenous catheter is placed and secured. Table 19-2 highlights the significance of abnormal physical examination findings.

19.9.1

NEONATAL CHARACTERISTICS INFLUENCING FLUID AND DRUG THERAPY[186]

It is often observed that neonatal animals are more “sensitive” to the actions of drugs administered at normal adult dosage levels (on a mg/kg bwt basis) and less tolerant of inappropriate fluid administration than adult animals. Differences between neonatal and adult animals in drug effects generally can be attributed to differences in drug distribution, metabolism, or excretion. Some general characteristics of the neonatal period include better absorption of drugs from the GI tract, less drug binding to plasma proteins, increased apparent volume of distribution of drugs that are distributed in the extracellular fluid (ECF) volume, increased permeability of the blood-brain barrier, and slower elimination (i.e., longer half-life) of many drugs. It is important to remember, however, that the foal and the calf are relatively precocious newborns, and much of the data on neonatal differences were generated in considerably less mature species. For instance, glomerular filtration rate (GFR) reaches adult values at 2 days of age in calves versus at least 14 days of age in puppies. Studies of the development of renal function in foals,[187] as well as indirect evidence provided by pharmacokinetic studies of antibiotic agents eliminated primarily by renal excretion,[188] suggest that full-term, 2- to 4-day-old foals also have relatively mature renal function. For a more detailed discussion of neonatal drug disposition, the reader is referred to other texts.[186,189,190]

In the neonate, the relative volumes of fluid differ from those in the adult. Total body water in the equine neonate constitutes 70% to 75% of the total body weight, versus approximately 60% in the adult horse. During growth the intracellular fluid compartment remains relatively consistent with regard to size, whereas the ECF compartment decreases as a percentage of body weight, with an increasing body fat percentage. In the 2-day-old foal, ECF volume was 394 ± 29 mL/kg, blood volume was 151 ± 32.8 mL/kg, and plasma volume was 94.5 ± 8.9 mL/kg; at 4 weeks at age, ECF volume was 348 mL ± 45 mL/kg and plasma volume was 61.9 ± 5.9 mL/kg.[191] In another study, in a 1-week-old term foal, ECF volume was 44 ± 1.3% of body weight and plasma volume was 6.5 ± 1% of body weight. The ECF volume at 3 weeks of age had decreased to 28 ± 2% of body weight.[192]

Although the neonate has a higher percentage of total body water than the adult, it is more vulnerable to water loss than the adult for several reasons, including increased basal metabolic rate; relatively greater surface area, predisposing to increased heat and water losses; and reduced urine concentrating ability.

Table 19-2 Physical Examination: Normal and Abnormal Parameters

Parameter	Normal Finding	Abnormal Observation
Attitude	Bright, alert	Depression: sepsis, hypoxia, pain, metabolic disturbances (acidosis, hypoglycemia) Seizures: hypoxic brain damage or meningitis
Body tone	Erect head and neck posture	Hypotonia: sepsis, immaturity, hypoxia Extensor rigidity: hypoxia, meningitis
Suckle reflex	Present <20 min after birth	Absent or weak with sepsis, immaturity or hypoxia
Body temperature	37.2° C-38.6° C (99° F-102° F)	Fever with well-established infection, hypothermia with acute sepsis Temperature instability with prematurity
Mucous membranes	Pink, moist	Pale membranes: anemia from excessive umbilical cord hemorrhage, blood loss into body cavities associated with birth trauma, hemolysis due to NI or DIC Icteric: liver disease, EHV-1 infection, sepsis, NI Cyanotic: shock, hypoxia Hyperemic: sepsis
Capillary refill time	<2 seconds	2 seconds with dehydration, shock
Petechiation	Absent	Present with DIC, sepsis
Pulse	70–100 bpm, regular	Tachycardia: fever, pain, shock, sepsis, hypocalcemia Bradycardia: severe septic shock, hypothermia, hypoglycemia, hyperkalemia
Pulse quality	Strong peripheral pulses	Hypotension: hypovolemic and septic shock; hyperkinetic pulses during early sepsis
Respiration	30–40 breaths/min, regular	Tachypnea: stress, pain, fever, lung disease, acidosis; slow, irregular rate with apnea caused by hypoxia, prematurity
Nostril flare, rib retractions	Absent	Increased with impending respiratory failure, pneumonia
Lung sounds	Easily heard all over chest	Rales, rhonchi, ventral dullness with pneumonia, consolidation, atelectasis
Eyes, eyelids	Clear cornea, no entropion	Blepharospasm, miosis, lacrimation, corneal edema and ulceration with self-trauma during recumbency and entropion
Abdominal distention; borborygmi	Distention absent; borborygmi heard on both sides of abdomen	Distention with ileus, hypoxic gut damage, meconium impaction, uroperitoneum, enteritis; borborygmi decreased with ileus and increased with enteritis
Fecal volume, consistency; color	4–6 oz two to four times per day; pasty; yellow or tan color	Constipation with meconium impaction, dehydration Diarrhea: sepsis, hypoxic gut damage, diet changes

Urine volume, concentration	4–6 mL/kg/hr; dilute, with specific gravity usually <1.020	Decreased volume with renal failure, hypoxic kidney damage, dehydration, ruptured bladder
Umbilicus	Dry, small	Moist and inflamed because of infection, urachal patency
Joints	No distention or lameness	Warm, distended joints, lameness with septic synovitis
Limbs	Straight with mild carpal valgus common	Tendon laxity with immaturity; carpal and fetlock contracture associated with fetal malpositioning, hypothyroidism, plant toxins

DIC, Disseminated intravascular coagulation; *NI,* neonatal isoerythrolysis; *EHV,* equine herpesvirus.

19.9.2

BASIC FLUID THERAPY IN THE FOAL

The goal of fluid therapy is to expand vascular volume in an attempt to restore and maintain cardiovascular function, improve organ perfusion pressure, and correct dehydration, acid-base balance, osmolality, and electrolyte disturbances. Fluid therapy is a crucial part of the supportive care of the abnormal neonate. In assessment of the need for fluid therapy, both the state of hydration (sunken eyeballs, decreased skin turgor, dry mucous membranes, generalized weakness, decreased urine output) and the state of circulating volume (heart rate, pulse quality, capillary refill time, temperature of limbs, BP) should be assessed. If the losses are very acute, gross abnormalities in effective circulating volume may not yet be reflected in decreased skin turgor or sunken eyeballs, but heart rate or pulse quality may be abnormal. On the other hand, pulse quality and perfusion may be relatively normal in a neonate with severely sunken eyes and reduced skin turgor. Neonates that appear very thin and malnourished may actually be very dehydrated; with fluid therapy alone, their appearance can dramatically change in a short period. In sick foals fluid therapy should replace existing deficits while supplying maintenance requirements. A foal with moderately to severely sunken eyes is estimated to be 8% to 10% (of body weight) dehydrated. The estimated fluid deficit in a 40-kg animal that is 10% dehydrated would be approximately 4 L.

Laboratory parameters are useful for formulating a fluid therapy plan. Serum electrolyte concentrations may be life-threateningly deranged in foals with a condition such as uroperitoneum or enteritis, and knowledge of specific values can be of great benefit in selection of an appropriate fluid. The affordability of portable blood chemistry analyzers (e.g., IRMA Blood Analysis System, Diametrics Medical, St. Paul, Minn.) makes determination of electrolyte values feasible even in field situations. Poor nursing in a neonate can be detected by measurement of urine specific gravity. The normal nursing foal produces large quantities of dilute urine (specific gravity 1.000 to 1.012). In some cases, laboratory values can be misleading. For example, PCV or total plasma protein is often within the normal range in clinically dehydrated neonates.

326

327

The fluid therapy plan is calculated to supply maintenance needs and to replace deficits and current losses. Calculation of fluid deficits is based on the following equation:

$$\textbf{Replacement fluid deficits}\,(L) = \%\ \textbf{Dehydration} \times \textbf{Body weight}\,(\text{kg})$$

Table 19-3 lists fluid replacement volumes for foals based on clinical assessment of dehydration.

Foals experiencing septic or hypovolemic shock may require fluid administration rates of 40 to 80 mL/kg/hr initially until their BP is stable. Normal BP ranges are as follows:

Systolic BP = 80 to 120 mm Hg

Diastolic BP = 65 to 90 mm Hg

Mean BP = 70 to 100 mm Hg

BP can be easily measured indirectly using the coccygeal artery and the noninvasive Doppler or oscillometric method.[193]

The maintenance fluid requirement for a newborn foal is approximately 4 to 6 mL/kg/hr (200 to 300 mL/hr for a 50-kg foal). Maintenance fluid administration in large animal neonates at the rate of approximately 100 mL/kg/day has usually resulted in adequate fluid balance and good urine output, in the absence of fluid deficits or increased fluid losses. If severe diarrhea is present, the daily fluid requirements can reach 15 to 20 L (500 mL/kg/day) or more.

If an animal is mildly to moderately dehydrated and the GI tract is not seriously compromised, fluid requirements can be provided by the enteral route, using milk or commercially available dextrose and electrolyte mixtures. However, if the gut is abnormal or if moderate-to-severe dehydration is present, the intravenous route is the preferred method of fluid administration.

Many types of intravenous catheters are suitable for use in the large animal neonate. Teflon catheters tend to be more thrombogenic than Silastic or polyurethane catheters and therefore should be replaced at more frequent intervals. A 5-inch long, 16-gauge Teflon catheter (Abbocath, Abbott Hospitals, North Chicago, Ill.) placed in the jugular vein and a 2-inch, 16-gauge Teflon catheter (Quik-Cath, Baxter Healthcare Corporation, Deerfield, Ill.) placed in the cephalic vein have both worked well to deliver intravenous fluids to foals. Short catheters placed in peripheral veins can be difficult to maintain and are not suitable for large-volume, rapid fluid replacement. I prefer to use a long-term, 16-gauge, 8-inch, polyurethane catheter (Arrow Catheter, Arrow International, Reading, Penn.) inserted in the jugular vein. This catheter is inserted over a flexible J-wire and can be left in place for 2 to 3 weeks. The use of polyurethane catheters reduces the incidence of thrombophlebitis and eliminates the need for frequent catheter replacement. Smaller-diameter catheters may be more suitable for lambs and kids. Regardless of the type used, it is essential to use aseptic techniques for catheter placement and to secure the catheter firmly to the skin. A combination of superglue and sutures has been very effective in keeping the catheters in place. Catheter sites are kept as clean as possible, and the site of venipuncture and the vein are watched closely for signs of infection. Specific information on catheter placement and maintenance can be found in other texts.[194,195]

Table 19-3 Calculation of Fluid Deficits

Severity of Dehydration	% Dehydration	Fluid Deficits for 50-kg Foal
Mild	5–6	2.5–3 L
Moderate	7–8	3.5–4 L
Severe	10	5 L

The intraosseous infusion technique is an alternative method for rapid delivery of fluids in the critically ill neonate when IV access is not possible. This procedure uses the intramedullary vessels in the bone marrow to gain access to the central circulation. A description of this technique is described in other texts.[196] The optimum type of intravenous fluid administered depends on the electrolyte and acid-base status of the patient. Fluids are available as either crystalloids (e.g., polyionic fluids such as Plasmalyte, Normosol, lactated Ringer's, saline) or colloids (e.g., plasma, hetastarch). Polyionic fluids are usually used for rapid rehydration and maintenance fluid therapy. These fluids should be isotonic (osmolality 270 to 300 mOsm/L). In most circumstances, in the absence of appropriate laboratory services the use of a balanced electrolyte solution such as lactated Ringer's or Plasmalyte is satisfactory to replace fluid deficits. Saline solutions may be a more appropriate choice in certain situations: foals with diarrhea are often hyponatremic and hypochloremic; premature foals with immature renal and endocrine function conserve electrolytes poorly and have a tendency to become hyponatremic and hypochloremic; foals receiving diuretics often require additional sodium chloride. Other exceptions to this rule include animals with hyperkalemia, in which potassium-containing fluids are best avoided, and animals with hypernatremia, in which controlled slow reduction of body sodium content is required.

Fresh or frozen plasma is often more effective than crystalloid fluids for volume expansion in seriously ill neonates. Endotoxemia and sepsis produce inflammatory changes in vessel walls. Capillary endothelial permeability is increased, resulting in increased extravasation of fluid and albumin from the capillaries into the interstitium. Rapid infusion of large volumes of crystalloids reduces colloidal oncotic pressure while transiently increasing intravascular hydrostatic pressure. These forces favor movement of fluid out of vessels. Colloidal solutions contain large—molecular—weight molecules that do not freely pass though the capillary membrane. Therefore colloid administration results in increased plasma oncotic pressure, increased plasma volume, and more effective improvement in circulating blood volume. There are synthetic colloids (e.g., dextran, hetastarch) and natural colloids (e.g., plasma, whole blood). Plasma has several advantages over synthetic colloids. It is a good source of protein, opsonins, complement, clotting factors, and immunoglobulins. The disadvantages of plasma include the possibility of an anaphylactic reaction and the need to thaw frozen plasma, which makes it less suitable when rapid fluid resuscitation is necessary. An effective, commercially available synthetic colloid is hetastarch (Hespan, DuPont Pharma, Wilmington, Del.). Hetastarch has been used successfully for rapid fluid resuscitation in equine patients and has caused few adverse reactions.[197]

If a neonate remains hypotensive in spite of volume expansion and fluid replacement, pressor agents such as dopamine and dobutamine may be indicated. Dopamine, with its combined α- and β-adrenergic and dopaminergic activity, is preferred. Higher doses will be required for patients in severe septic shock. If the foal fails to respond to high doses (>10 to 15 μg/kg/min), then norepinephrine, a more potent α-adrenergic agent, can be tried. Safe and effective infusion of these agents requires continuous monitoring and some type of infusion pump. Recently, nitric oxide (NO) has been shown to play a role in sepsis-induced hypotension.[198] IV administered new methylene blue, an NO antagonist, has been used to try to reverse severe life-threatening hypotension.

327

328

The rate of fluid administration is determined by the degree of dehydration, severity of cardiovascular compromise, and maintenance requirements. Most normal foals can tolerate rapid fluid infusion, but asphyxiated, septic, or premature foals may be oliguric and therefore far less tolerant of overzealous fluid administration. In these cases generalized edema may result. A general rule of thumb is to replace one half the calculated deficit in the first 6 hours of fluid therapy and the rest over 12 to 24 hours. A flow rate of 20 mL/kg/hr or higher (40 to 80 mL/kg/hr) may be needed to treat hypovolemic or septic shock.

In any depressed, weak, or seizuring animal, blood glucose levels should be checked, because hypoglycemia is one of the most frequently observed metabolic derangements accompanying many neonatal diseases. The rapid blood glucose reagent strips and hand-held Glucometers are very useful in making this determination in a field setting. For treatment of hypoglycemia a continuous infusion of 5% to 10% dextrose is sufficient to reach and maintain adequate blood glucose levels in most neonates. Hypertonic glucose boluses (25% to 50%) may aggravate preexisting CNS insults and frequently result in rebound hypoglycemia 30 to 40 minutes after infusion. Therefore they should be avoided. One regimen for treating hypoglycemia is 10% dextrose infusion administered at 5 to 10 mL/kg fairly rapidly, followed by a continuous infusion to supply 4 to 8 mg/kg/min (approximately 5 mL/min of 5% dextrose for a 40-kg neonate). The appropriateness of the therapy should be judged by frequent blood and urine glucose determinations. If hyperglycemia results, the rate of infusion or concentration of solution is decreased (to deliver perhaps 2 mg/kg/min) but not stopped.

Another metabolic derangement commonly observed in the large animal neonate is metabolic acidosis. This disorder may be caused by accumulation of acid, by loss of buffers from the body, or by a combination of the two. Whenever possible, treatment should be directed at correcting the underlying cause of the acidosis. Acidosis caused by low cardiac output or decreased peripheral oxygen delivery should be treated by measures to increase tissue perfusion (e.g., plasma volume expansion, cardiac inotropes, nasal oxygen insufflation). In this type of acidosis there is no actual loss of bicarbonate from the body, and bicarbonate therapy often produces disappointing results and adverse reactions. If respiratory dysfunction is present, considerable caution should be exercised in the use of sodium bicarbonate. Bicarbonate functions as a buffer only in an “open” system in which carbon dioxide can be transported to the lungs and eliminated.[199] Profound fluctuations in BP and cerebral blood flow, intracranial hemorrhage, and decreased oxygen delivery to tissues are possible adverse effects of sodium bicarbonate infusion in human beings.[200] In many mildly to moderately acidotic neonates, simple volume expansion with isotonic fluids alone is very effective in correcting the base deficit by improving perfusion. Other more compromised individuals need more aggressive support of the cardiovascular system. Mild acidosis (HCO_3 deficit 5 to 10 mEq/L) associated with dehydration, can be corrected by simple rehydration. Bicarbonate supplementation is recommended when HCO_3 deficits are >10 mEq/L (serum HCO_3 <15 mEq/L) or whenever the pH is <7.2. Bicarbonate deficits can be calculated using the following equation:

$$\text{Bicarbonate deficit (mEq)} = 0.6 \times \text{Body weight (kg)} \times \text{Base deficit (mEq)}$$

An isotonic bicarbonate solution is preferred because excessive bicarbonate administration results in increased CO_2 production, leading to respiratory embarrassment and increased risk of CNS acidosis and hemorrhage. Isotonic bicarbonate can be made by adding 150 mL of 8.4% bicarbonate solution to 850 mL of sterile water, or 200 mL of 5% bicarbonate solution to 800 mL of sterile water. Bicarbonate solutions should be given slowly. Hyperkalemia is often observed with metabolic acidosis because of the transcellular shift of potassium ions into the ECF in exchange for hydrogen ions.[201] As the metabolic acidosis is corrected, the hyperkalemia resolves. Bicarbonate solution should not be combined with any calcium containing solution or precipitation will occur.

The effect of the bicarbonate replacement therapy should be monitored closely, and the dose adjusted accordingly. Neonates with severe diarrhea because of ongoing losses of bicarbonate through the feces may need considerably more than the calculated deficit to maintain an adequate blood pH until the diarrhea subsides. As in any type of fluid therapy, a plan is devised, the animal's response to the plan is monitored, and changes are made accordingly.

Hypokalemia can occur in anorexic foals, foals with diarrhea, and those receiving diuretic therapy. Potassium (K) supplementation can be estimated using the following equation:

$$\text{Replacement K (mEq)} = 0.4 \times \text{Body weight (kg)} \times \text{K deficit (mEq)}$$

Potassium can safely be added to fluids at a rate of 20 to 30 mEq/L. The rate of potassium administration should not exceed 1 mEq/kg/hr. If acidosis is present, hydrogen ions are exchanged for intracellular potassium ions, resulting in a relative increase in serum K. As the acidosis is corrected there will be an influx of K ions back into cells, resulting in potential hypokalemia, which must be anticipated during fluid therapy.

19.9.3 NUTRITIONAL SUPPORT OF THE ABNORMAL NEONATAL FOAL

Provision of adequate nutritional support to the compromised neonate is an essential part of critical care but often becomes a major management problem. Reasons for the common failure to provide adequate nutrition to the neonate include underestimating the needs of the ill, stressed animal; a disinterest in nursing on the part of the sick neonate; the need to use alternate methods and routes of delivery for continued oral feeding; and a GI tract that is compromised and intolerant of nutrient intake.

Nutrition of the premature or sick neonate is a science that is in its early stages of development even in human neonatology; much less is known in veterinary medicine. The exact nutritional requirements for optimum growth of the normal-term foal have not even been defined, let alone for the premature, growth-retarded, or debilitated animal whose caloric, protein, mineral, and vitamin requirements might be very different.

Measurements of milk production of mares combined with data concerning the free-choice milk intake of normal orphan foals and premature and sick foals recovering from various illness suggest that a figure of 125 to 150 kcal/kg/day or even higher is close to the normal caloric intake.[202] Healthy full-term foals nurse an average of 2 minutes, seven times an hour,[203] consume between 20% and 30% of their body weight in mare's milk daily, and gain 0.5 to 1.4 kg/day. On this diet a 50-kg foal would consume 10 to 12.5 L of milk a day to receive 120 to 150 kcal/ kg/day. Nutritional requirements may be even higher in disease states such as generalized septicemia, pulmonary disease, or thermal stress or after surgery.

If there is no medical contraindication for oral feeding, and if the GI tract is functional, then enteral nutrition is the preferred and most effective route of nutritional supplementation. Enteral feeding is more physiologic and stimulates normal gut maturation, growth of intestinal villi, production of crypt cells, and hepatic and biliary secretions and brush border disaccharidase enzyme activity. Enterocytes rely on absorption of volatile fatty acids (VFAs) such as glutamine and β-hydroxybutyrate from the gut lumen as their primary energy source. Therefore, even in foals that must be fed parenterally, small volumes of enteral feeds are given to “feed the gut” to prevent gut atrophy.

328

329

Foals that are not nursing from the mare can be fed by bottle, bucket, or nasogastric tube. If an effective swallow reflex is present, then bottle-feeding can be used. Udder-bumping and teat-seeking behavior can be stimulated by allowing the foal to approach the bottle from behind and under the handler's armpit. This technique also reduces the risk of aspiration by preventing overextension of the head and neck. Bucket-feeding allows the foal to drink with its head and neck in a flexed position and is helpful for foals with a weak swallow reflex or foals destined to be hand-raised. Milk should be introduced in a shallow handheld bowl and the foal encouraged to suckle the finger or nipple as its head is lowered into the milk. “On demand” feeding is ideal but often impractical and labor intensive. Foals less than 7 days of age should be fed every 2 hours.

Nasogastric intubation is required if ineffectual swallowing and suckling are present. A small-bore flexible silicone tube (5 to 7 mm internal diameter) with a weighted tungsten end is preferred. Individual choice dictates whether the tube is passed for each feeding or left indwelling. Indwelling tubes can be sutured to the nares or

taped to half a tongue depressor, which is then taped to the foal's muzzle and/or fleece halter. Tubes should be sealed between feedings to prevent aerophagia. Recumbent foals should be maintained in sternal recumbency immediately after tube-feeding to reduce the risk of gastroesophageal reflux and aspiration.

If the foal's mother is available and milk production is adequate, free-choice nursing is optimal. A nurse mare is probably the next best substitute. Popular enteral formulas include mare's milk, goat's milk, and artificial milk replacers. Mare's milk is preferred. Goat's milk is acceptable and is higher in fat, total solids, and gross energy than mare's milk Foals raised on goat's milk occasionally become constipated. Cow's milk is not as digestible but can be used if additional sugar is added and some of the fat is removed. This can be accomplished by using 2% skim milk and adding 20 g of dextrose per liter of milk. Various artificial milk replacers are available. The ideal replacer should have 22% crude protein, 15% fat, and less than 0.5% fiber on a dry matter basis. Complications associated with enteral feeding include colic, abdominal distention, diarrhea, constipation, flatulence, misplacement of the nasogastric tube, aerophagia, nasal and pharyngeal irritation from the tube, and aspiration pneumonia.

Delayed gastric emptying and gastroduodenal dysmotility can be improved in some foals with metoclopramide given IV as a slow infusion (0.25 mg/kg/hr) or orally (0.3 to 0.6 mg/kg q4-6h). Overdosage is associated with excitement. Other prokinetic agents are erythromycin (1 mg/kg PO four times per day [qid] or given as a 30-minute infusion qid), which works throughout the GI tract, and cisapride (0.1 to 0.2 mg/kg PO or per rectum q6h), which also affects the entire gut. All prokinetic agents are contraindicated if GI obstruction is suspected. Diarrhea is treated symptomatically with oral bismuth subsalicylate (1 to 2 mL/kg PO q4-6h) and/or loperamide (0.1 to 0.2 mg/kg PO q6h). Diarrhea may also respond to administration of active culture yogurt or an intestinal inoculant containing lactobacillus organisms. Nasopharyngeal irritation from repetitive tubing can be treated with insufflation of a nasopharyngeal spray containing prednisone, Furacin, glycerin, and DMSO.

More details on the feeding of both orphan and sick neonatal foals are contained in review papers[202,204–207] and in Chapter 50.

19.9.4 PARENTERAL NUTRITION

During the past years, PN has been more frequently used to supply at least a portion of the daily nutritional requirements to critically ill foals and calves. PN is indicated whenever feeding via the gut is inadequate or contraindicated. Candidates for partial or total PN include individuals with chronic diarrhea, those with GDUD (foal), a variety of postsurgical patients, foals with botulism, premature and infected animals, and other individuals with GI tracts poorly tolerant of enteral feedings.

PN involves administration of hypertonic solutions containing dextrose, amino acids, lipids, vitamins, electrolytes, and trace minerals. These PN solutions must be administered continuously through a jugular catheter. Complications include metabolic disturbances such as hyperglycemia, hypoglycemia, glucosuria, osmotic diuresis, hyperlipemia, azotemia, and imbalances of trace minerals, vitamins, and electrolytes. Catheter-related problems include thrombosis, phlebitis, and sepsis. Commonly used stock solution for PN include 50% dextrose, 8.5% or 10% amino acids, and 10% or 20% lipid emulsion. Sample calculations are as follows:

Initial Formulation for a 50-kg Foal	
Glucose	10 g/kg/day = 450 g = 900 mL of 50% dextrose
Amino acid	2 g/kg/day = 90 g = 900 mL of 10% amino acid
Lipid	1 g/kg/day = 45 g = 450 mL of 10% lipid
Calories Provided	
Glucose	3.4 kcal/g; 450 g = 530 kcal
Amino acid	4 kcal/g; 90 g = 360 kcal
Lipid	9 kcal/g; 45 g = 495 kcal
Total calories	2385; 53 kcal/kg/day

Source of Calories
Glucose = 64%
Amino acid = 15%
Lipid = 21% (foals should not receive more that 50% of nonprotein calories from lipids)

Nonprotein Calories/Gram of Nitrogen
NP calories = 2025
6.35 g protein = 1 g nitrogen
90 g amino acid = 14.4 g nitrogen
Nonprotein calories/ g of nitrogen = 2025/14.4 = 140.6 (to prevent catabolism of protein for energy, the ratio should be between 100 and 200)

Supplements
Multivitamin concentrate (pediatric formula), trace mineral (MTE-5), KCL 20 to 40 mEq/L

Foals receiving PN should have their blood and urine glucose monitored. Serum glucose concentration should remain >80 mg/dL and <180 mg/dL. Serum should be checked for gross lipemia. Heparin can be administered at 10 units/kg as an intravenous bolus to treat lipemia. The amount of glucose, lipid, and amino acids can be varied for each individual foal. Foals must be weaned onto and off of PN slowly. All intravenous lines must be checked

routinely for signs of infection. Additional information regarding the use of PN in foals is presented in other articles.[207]

At the present time, the applications of PN are on a fairly short-term basis compared with human medicine—usually 2 to 3 weeks at the most. Most commonly, parenteral and enteral nutrition has been used in combination; parenteral nutrient delivery is used to supplement, not totally replace, oral intake. Enteral nutrition helps to maintain the intestinal mucosa. Prolonged total PN is associated with reduced intestinal epithelial cell renewal, villous atrophy, and decreased enzymatic activity.[208]

329
330

Although PN can be expensive and difficult to manage, the benefits, such as prevention of a catabolic state or starvation, improved body condition at discharge, and better healing, can far outweigh the drawbacks. Details concerning the use of PN compounds can be found in other references[209] and in Chapter 50.

19.10 NOSOCOMIAL AND ZOONOTIC INFECTIONS

Immunologically naive neonates are particularly susceptible to opportunistic and contagious pathogens. Nosocomial infections increase mortality and amplify environmental contamination, perpetuating further dissemination of the infecting organism. Prevention of nosocomial infection requires attention to detail. Patients may be exposed to pathogens via environmental contamination, biologic vectors, equipment, and personnel. Provision of a pathogen-free environment requires disinfection between patients and verification of disinfection via culture. Control of vermin is important, as birds, rodents, and insects have all been implicated in dissemination of infectious pathogens. Equipment (shovels, brushes, nasogastric tubes, etc.) function as vectors if not disinfected between stalls and/or animals. And, most important, personnel have to appreciate their potential role in nosocomial infections. Personnel schedules need to take into consideration the workload demands and the implications such demands may have on infectious disease control over all 24 hours of each day. Separate personnel for management of infected and high-risk patients is desirable. Attention to detail, basic hygiene, and common sense prevail. Washable footwear, disinfectant footbaths, patient-specific protective clothing, and hand washing between patients are infectious disease control protocols that have been successfully applied in controlling infectious disease outbreaks in veterinary hospitals. Many of the pathogens that affect neonates are potentially zoonotic (*salmonella, cryptosporidium, giardia,* and *clostridium*); personal hygiene is in the interest of the health care provider and the patients.

19.10.1 IMMUNE SYSTEM SUPPORT: PLASMA AND COLOSTRUM

Controversy persists as to what serum IgG concentration is protective for newborn foals. There is little argument, however, that healthy foals have postsuckle IgG exceeding 1000 to 2000 mg/dL within 24 hours of birth. There is also agreement that there is a correlation between very low IgG concentrations (IgG <200 mg/dL) and increased foal morbidity and mortality. By definition, IgG <200 mg/dL is complete FPT, and IgG between 200 and 800 mg/dL is partial FPT. Causes of FPT include poor-quality colostrum, failure to ingest adequate colostrum, and inability to absorb adequate amounts of colostral immunoglobulins. Mares produce an average of 1.5 to 2 L of colostrum. Ideally, foals should receive a minimum of 1 L of good-quality colostrum within the first 8 hours of life. In addition to IgG, colostrum contains IgA for local gut immunity, IgM, high caloric density, growth factors, lactoferrin, laxative properties, and leukocytes. If fresh or frozen colostrum is not available, some sources of lyophilized IgG products for oral administration have a longer shelf life and do not require freezing. These products are expensive and may have variable absorption. Regardless of the product, a rule of thumb is to administer a minimum of 40 g of IgG (or 1 g/kg of body weight) to colostrum-deprived foals. Always measure serum IgG concentrations to determine if the supplementation was adequate.

Plasma administration becomes necessary if the foal's IgG is low and the foal is too old to absorb colostrum or gut function is abnormal. I recommend IgG supplementation for any foal with a serum IgG <200 mg/dL regardless of its health status or environment. If the foal's IgG is between 200 and 800 mg/dL, I recommend IgG supplementation if one or more of the following conditions exist:

Gestation length <320 days, or signs of prematurity or dysmaturity

Difficult delivery (e.g., dystocia, premature placental separation, meconium staining)

Grossly abnormal or heavy placenta (>11% of foal's body weight)

5- and 10-minute Apgar scores <6

High environmental stresses including overcrowding and poor farm hygiene

Anticipated transportation off the farm within 7 to 10 days of foaling

Failure to stand and nurse within 3 hours of delivery

Abnormal physical examination within 24 hours of birth; significant abnormalities include generalized weakness, injected mucous membranes, poor suckle, severe angular limb deformities, enlarged umbilicus, patent urachus, colic, meconium retention, increased respiratory effort, other signs of localized infection

Poor postpartum surveillance

Plasma is administered through an aseptically placed catheter using a blood administration set with an in-line filter. The volume of plasma to give depends on the foal's IgG, the desired IgG, the foal's body weight, and the IgG in the plasma and the general health of the foal. The old rule of thumb for plasma administration for FPT is 20 mL/kg or approximately 1 L for a 45-kg foal. In healthy foals, 1 L of plasma with IgG of 1200 mg/dL raises the serum IgG 200 to 250 mg/dL. The same amount of plasma has less effect in foals with sepsis. Ill foals require relatively more plasma because the serum half-life of IgG is less, IgG may be sequestered in intravascular spaces or at sites of inflammation, and IgG may be catabolized more readily. A complete discussion of FPT and its treatment is presented in Chapter 53.

Plasma should be administered at an average rate of 10 mL/kg/hr. Give the first 100 mL slowly, and monitor the foal's pulse, respiratory rate, and temperature. Possible transfusion reactions and treatment for such reactions are listed in Table 19-4.

19.10.2 RESPIRATORY SUPPORT

Thoracic radiographs and ABG analysis help determine the severity of lung disease. Lateral radiographs with the foal standing or recumbent help characterize the nature and extent of pulmonary pathology. Diffuse pulmonary

infiltrates occur with bacterial and/or viral pneumonia and atelectasis. Cranioventral and caudoventral pulmonary infiltrates are seen with aspiration pneumonia and bacterial bronchopneumonia. Nodular infiltrates suggest discrete abscessation.

ABG analysis determines the degree of pulmonary dysfunction. Portable blood gas machines now make blood gas analysis easy and affordable. The preferred site for arterial puncture is the great metatarsal artery. A small 25-gauge needle attached to a heparinized 1- or 3-mL Luer slip syringe is used. Hypoxemia (Pa_{O_2} <60 mmHg) with a normal Pa_{CO_2} is caused by ventilation-perfusion mismatching, right-to-left shunting, low inspired O_2, and impaired gas exchange. Hypoxemia accompanied by elevated concentrations of CO_2 is usually the result of hypoventilation caused by respiratory muscle fatigue, central depression of the respiratory center, or neuromuscular weakness as with botulism. Mild hypoxemia can be improved by positioning the laterally recumbent foal into a sternal position. Oxygen supplementation is best administered through a soft nasal cannula inserted into the nasal passage to the level of the medial canthus. The cannula can be sutured or taped to the external nares. Humidified oxygen is administered using a tank or wall oxygen source and a humidifier filled with distilled water. Oxygen flows between 2 and 10 L/min are regulated using a flowmeter. Flow rates are adjusted to keep the Pa_{O_2} between 70 and 100 mm Hg. Long oxygen lines attached to a surcingle allow even ambulatory foals to benefit from continuous oxygen therapy.

Table 19-4 Transfusion Reactions: Signs, Causes, Therapy

Signs of Reaction	Cause	Treatment
Hemolysis, hemoglobinuria, hemoglobinemia	Incompatibility between donor RBCs and recipient's plasma	Stop transfusion; give IV fluids; cross-match for suitable donor
Fever, chills	Allergic or nonspecific reaction to donor protein	Give antipyretics
Allergic reaction, urticaria	Recipient reacts to soluble antigens in donor's plasma	Slow transfusion, give antihistamine
Anaphylactic reaction, respiratory distress, hypotension, shock	Anaphylaxis	Stop transfusion, give epinephrine (5–10 mL of 1:10,000 epinephrine via IV or SC route)
Circulatory overload, hypertension, pulmonary edema, cardiac dysfunction	Excessive volume expansion	Stop or slow transfusion; give diuretic
Endotoxemia, fever, tachycardia, tachypnea, leukopenia	Contaminated transfusion	Stop transfusion, give Banamine, and antibiotics

IV, Intravenous; *RBCs,* red blood cells; *SC,* subcutaneous.

Mechanical ventilation is necessary for persistent hypoxemia that is refractory to nasal insufflation or is accompanied by Pa_{CO_2} >70 to 75 mm Hg. A long, cuffed nasotracheal tube is required, as is a ventilator capable of delivering tidal volumes of 10 to 15 mL/kg, respiratory rate of 15 to 25 breaths per minute, proximal airway pressure between 18 and 25 cm H_2O, end expiratory pressure (PEEP) of 0 to 10 cm H_20, and an inspired oxygen concentration between 0.21 and 1.0. Ventilators that allow the foal to breathe spontaneously between preset ventilator-delivered breaths are tolerated the best by the foal. Guidelines regarding ventilatory support for foals

are presented in other review articles.[70] More recently there have been investigations using noninvasive mechanical ventilation in neonatal foals.[72]

Foals have a poorly developed cough reflex. Tracheobronchial secretion removal may be enhanced using chest coupage and nebulization with mucolytic agents such as acetylcysteine or dilute bicarbonate solution. Ultrasonic nebulizers using solutions or an Equine Aero Mask using metered dose aerosol inhalers can be used.

Chemical respiratory stimulants can be used to stimulate the central respiratory center. Theophylline, caffeine, and aminophylline are xanthine derivatives commonly used as bronchodilators but can also be used to improve diaphragmatic contractility and to treat periodic apnea associated with hypoxia and prematurity. The safest stimulant is caffeine: loading dose of 10 mg/kg PO once per day (sid) followed by 2.5 mg/kg PO sid as a maintenance dose.

19.10.3 ANTIBIOTIC THERAPY

Foals that become ill or compromised during the first few days of life are at increased risk for infection. Because of the neonate's immature immune system, localized infections tend to become systemic, leading to septicemia. This explains how foals with diarrhea can develop uveitis and septic joints. Antibiotics are administered to foals for two reasons: prophylactically to prevent infection, and therapeutically to treat existing infection. The most serious infections are those caused by gram-negative bacteria (e.g., *E. coli, Klebsiella, Salmonella, Pasteurella, Actinobacillus)*. The most common gram-positive pathogen is *Streptococcus* species, which are often encountered as part of a mixed infection involving the respiratory tract and umbilicus. Occasionally, anaerobic infections (e.g., *Clostridium, Bacteroides)* are encountered as causes of umbilical infections, diarrhea, or aspiration pneumonia.

When antibiotics are used prophylactically, the oral and intramuscular routes of administration can be considered. Penicillin or ampicillin and an aminoglycoside administered IM or IV are good choices if the risk of infection is great. Ceftiofur (IM) or trimethoprim-sulfamethoxazole (PO) are reasonable choices. Prophylactic antibiotics should be given for 3 to 5 days or until the risk factors for sepsis are gone. Once sepsis is confirmed, intravenous administration is the preferred route because gut absorption is too variable. Antibiotic therapy should be continued for a minimum of 7 to 10 days. If localized infections develop, then antibiotics may need to be given for 2 to 3 weeks. In cases of abscess formation and bone infections, therapy is often extended for 1 to 2 months.

19.10.4 TRANSPORT AND REFERRAL

A decision should be made early in the clinical course as to whether the neonate can be taken care of at the farm or whether it should be referred to a neonatal intensive care facility for treatment. If the support staff on a farm are experienced and committed to provision of good nursing care and if appropriate diagnostic facilities are available, many mildly to moderately ill individuals can be successfully treated on the farm and recover within 2 to 4 days. When the neonate is more compromised and in need of considerable supportive care, including 331
continuous intravenous fluid therapy and oxygen supplementation, a more rational decision is to refer, if the 332
